Abstract

Despite substantial growth in medical technology, there is limited causal evidence on the impacts of many medical innovations on health and disability. This paper investigates the impact of a major surgical innovation: the move from conventional open surgery to minimally invasive surgery. Using an instrumental variables research design along with administrative data on injured workers undergoing orthopedic surgery, we quantify the impact of minimally invasive surgery (compared to analogous open surgery) on subsequent health care use, return to work, long-term disability, and social insurance payments. The findings suggest minimally invasive surgery reduces health care spending in the two years following surgery by 30%—through both reduced complexity of the surgery itself and large reductions in subsequent health care use. Analysis by type of service suggests minimally invasive surgery reduces subsequent office visits, opioid use, and revision surgeries. Moreover, we document that minimally invasive surgery also improves broader measures of patient health and disability—speeding return to work (by 37 days), reducing the severity of permanent disabilities (by 30%), and reducing associated social insurance costs (by 28%). We conclude by documenting trends in the adoption of minimally invasive surgeries and exploring the policy implications of our findings.

There has been tremendous progress in medical technology over the last century. Such innovation has been credited with major improvements in health—through enabling life-saving interventions and promoting longevity. Beyond enabling longer lives, medical innovation also has the potential to improve quality of life. Despite the incredible promise of medical innovation, it is challenging to quantify the impacts of innovation on health for several reasons. First, measuring health is difficult—particularly at scale. Thus, much of the research analyzing the health impacts of innovation focuses on acute impacts of interventions that may plausibly impact mortality or hospitalizations. Second, identification is challenging. Many health care innovations—including nearly all non-pharmaceutical medical innovations—do not require clinical trials. When clinical trials are conducted, they tend to be small and explore a limited set of outcomes. Quasi-experimental approaches also prove difficult because they require both isolating plausibly exogenous variation and obtaining data on innovation exposure and outcomes. As a consequence of these measurement and identification challenges, causal evidence on the impact of medical innovation is scarce.

This paper addresses these challenges and provides novel evidence on the impact of an important medical innovation. Specifically, we focus on arguably the largest surgical innovation in the last several decades: the move from traditional “open surgery”—where a surgeon makes a large incision and performs a surgical intervention in the area uncovered by the incision—to “minimally invasive surgery”—surgery performed via small incision with the assistance of scopes (e.g., arthroscopic or laparoscopic surgeries). Since the initial development of minimally invasive methods, the medical community has recognized the potential for minimally invasive surgery to improve patient outcomes relative to conventional open surgery; the purported benefits of minimally invasive surgery include reduced pain, post-operative swelling, risk of complications, and recovery times. However, it is not *ex ante* obvious that minimally invasive surgery would yield these benefits. Some have raised concerns that the reduced visibility and accessibility inherent to these procedures could worsen outcomes—through inhibiting the surgeon’s ability to protect surrounding tissue, leading to unrecognized intraoperative errors, or presenting challenges when navigating difficult anatomical features such as deformity or poor tissue quality.¹ Despite the potential promise of these methods and the rapid growth in the use of these methods, existing evidence is limited to medical studies providing correlational evidence or small-scale evaluations of one particular surgery, and no broad causal evidence exists on the impacts of minimally invasive surgery.² This paper begins to fill this gap by providing novel large-scale causal evidence on the impact of minimally invasive surgery relative to conventional open surgery on a wide range of

¹For example, see Rosenberg (2016) for an in-depth discussion of the claimed benefits and potential risks associated with minimally invasive surgery.

²While there is a small medical literature comparing minimally invasive and open surgery, these studies have fundamental limitations. Most of these studies provide correlational evidence, and thus are unable to isolate causal impacts (e.g., Moran et al. 2023; Yasui et al. 2016; Truong et al. 2021). While a few clinical trials exist, they suffer from very small sample sizes (with a typical sample size ranging between 50 and 70), leaving them underpowered to detect meaningful differences (e.g., Hiemstra et al. (2008); Kang, Akelman and Weiss (2008); Raab et al. (1993); Kaufmann et al. (2019); Rodríguez-Vela et al. (2013)). Moreover, these trials typically focus on a single surgery and narrow immediate outcomes measured through surveys. No prior work offers large-scale causal evidence on the impacts of minimally invasive surgery relative to open surgery.

outcomes.

Our study estimates the impact of minimally invasive surgery relative to open surgery in the context of orthopedic surgery on the musculoskeletal system. Roughly a third Americans receive medical care for musculoskeletal conditions annually, making it one of the largest expenditure categories in health care. And estimates suggest the aggregate annual direct and indirect costs of musculoskeletal conditions are roughly 5.7% of GDP.³ Surgery is often used to treat musculoskeletal conditions, and orthopedic surgeries are among the most common surgeries. The number of orthopedic surgeries grew by 35% between 2001 and 2011, and, as of 2018, these surgeries account for 25% of all operating room procedures (excluding obstetrics).⁴ Moreover, the introduction of minimally invasive surgical techniques has dramatically changed how orthopedic surgery is done. Approximately three-quarters of orthopedic surgeries now use minimally invasive methods, and this share has increased by roughly 9.2% since 2008.⁵

Orthopedic surgery is generally considered low-risk surgery and is typically performed on a reasonably healthy population; thus, we may not expect modern innovation in orthopedic surgery to have large impacts on immediate post-surgical mortality from risks directly resulting from the surgery itself. Nevertheless, innovation in orthopedic surgery may have large impacts on health through affecting an individual's recovery from physical impairments necessitating surgery and recovery from the surgery itself. And these impacts may be long lasting, affecting an individual's healing trajectory and overall health for weeks, months, or years after the procedure. In this way, surgical innovation may have important impacts on overall health, daily living limitations, and the ability to resume normal activities including work—both in the short and long runs. We estimate the comprehensive impacts of surgical innovation on health, health care use, labor supply, and disability using comprehensive administrative data on injured workers in Texas.

Our analysis leverages comprehensive administrative claims data combined with a unique dataset we compile on surgeries that may be performed using either open or minimally invasive techniques. Using these data, we document that there is tremendous variation in whether a given surgery is performed using open or minimally invasive techniques, over time and across surgeons. After a minimally invasive technique is first developed for a particular surgery, adoption of this technique slowly diffuses over time, as knowledge and practices are disseminated through

³These statistics come from a report by the U.S. Bone and Joint Initiative (Yelin, Cisternas and Watkins-Castillo, 2020), which shows that the average annual proportion of the U.S. population with a musculoskeletal condition that requires medical care is 34%, and, in 2012 to 2014, the annual estimated direct and indirect costs attributable to musculoskeletal diseases (including health care costs and decreased wages) were nearly \$980 billion or 5.7% of GDP.

⁴According to a report by the Agency for Healthcare Research and Quality (AHRQ) (Weiss and Elixhauser, 2014), musculoskeletal procedures made up 17.9% of all procedures in 2001 and rose to 24.2% by 2011, representing a 35% increase. The figure cited here—25% of all operating room procedures (excluding obstetrics)—comes from combining information in a report by the AHRQ (McDermott and Liang, 2021b), which documents that orthopedic procedures accounted for 21.0% of all inpatient operating room procedures and that obstetric/gynecological procedures accounted for roughly 15.8% of procedures. As a share of major ambulatory surgeries (i.e., hospital-based outpatient surgeries), orthopedic surgeries account for 22% of all procedures (McDermott and Liang, 2021a).

⁵Based on the authors' calculations, between 2008 and 2020 there was roughly a 9.2% increase in the use of minimally invasive techniques for “target surgeries” analyzed in this paper—musculoskeletal surgeries that can be performed using either open or minimally invasive techniques—controlling for the composition of target surgeries over time. The share of target surgeries that were minimally invasive in 2020 was 73.2%.

professional networks and across regions. Widespread or near-universal adoption can take years or decades. As we demonstrate, at any given point in time, there is substantial variation across regions and across surgeons in the use of minimally invasive techniques for a given surgery. And we demonstrate this variation across surgeons leads to substantial overlap in the patients who receive minimally invasive surgery and those who receive open surgery among otherwise similar patients—patients with the same type of injury who reside in the same medical markets.

While the surgeon has substantial influence over the surgical method used, whether a given patient receives the open or minimally invasive version of the surgery may also depend on factors related to the patient or situation—e.g., health risk of the patient, circumstances of the surgery, or differences in the nature of the problem the surgery is meant to address. We demonstrate that whether a given patient receives the open or minimally invasive version of a surgery is strongly related to baseline patient and surgery characteristics. This presents a key identification challenge for estimating the causal effect of minimally invasive techniques. To overcome this challenge, our research design aims to isolate the plausibly exogenous variation in surgical method used across surgeons while removing the potentially endogenous factors. Specifically, we leverage an instrumental variables research design, where we instrument for whether a given patient receives the open or minimally invasive version of a surgery using the propensity of their surgeon to use minimally invasive methods among the surgeon’s other patients, while controlling for basic patient and surgery characteristics.

We apply this empirical design to estimate the impact of minimally invasive surgery among injured workers covered by workers’ compensation insurance. Workers’ compensation insurance provides workers with cash benefits to compensate for missed work due to workplace injuries and coverage for health care associated with these injuries. There are several strengths of this setting for this analysis. First, this is an important context to understand the impacts of minimally invasive surgery. Orthopedic surgeries address musculoskeletal injuries, and musculoskeletal injuries commonly occur at work and are associated with substantial costs. Three out of every 100 full-time workers in the U.S. experienced a workplace injury in 2022, and estimates suggest the annual aggregate costs of these injuries exceed \$250 billion.⁶ Workers’ compensation is one of the larger social insurance programs in the U.S., with benefits totaling \$63 billion in 2019—or roughly double the aggregate benefits paid through unemployment insurance that year and on par with aggregate benefits paid through the Earned Income Tax Credit or the Supplemental Nutrition Assistance Program.⁷ While workplace injuries vary in circumstances, the vast majority of workers’ compensation insurance claims are for musculoskeletal injuries and orthopedic surgery is commonly used to address such injuries.

Second, the administrative data on injured workers that we leverage are uniquely comprehen-

⁶See BLS (2022) and Leigh (2011).

⁷In 2019, the Earned Income Tax Credit paid out \$69.6 billion in benefits (TREAS, 2019); workers’ compensation insurance paid out \$63.0 billion in benefits (Murphy et al., 2021); the Supplemental Nutrition Assistance Program paid out \$55.6 billion in benefits (Kaiser Family Foundation, 2019); and unemployment insurance paid out \$27.3 billion in benefits (DOL, 2021).

sive. These data include all the typical information available in health care claims data, as well as several additional measures of health, disability, and labor supply, including the duration an individual is out of work receiving wage replacement benefits while recovering from their injury and measures of impairment that reflect a worker's degree of permanent disability after healing has plateaued. These data allow us to provide a comprehensive assessment of the impacts of minimally invasive surgery on health, disability, and social insurance outcomes.

Third, this setting is particularly well-suited for our research design. Both institutional details and empirical evidence support the plausibility of our key identification assumptions. Because the workers' compensation system uses a strict gatekeeper model, it substantially limits injured workers' influence over whether they receive surgery and which surgeon performs it. Moreover, we provide empirical support for the validity of the research design in this setting using several tests. For instance, we demonstrate that our instrument is a strong predictor of the actual technique used for the surgery. In addition, we use the rich baseline administrative data to illustrate that the instrument appears unrelated to baseline observables of the patient or injury—supporting the assumption that the instrument is independent of other determinants of outcomes. Finally, we show that other surgeon characteristics correlated with minimally invasive intensity do not explain our findings, supporting the exclusion restriction.

Our primary analysis investigates the impact of having minimally invasive surgery (relative to an analogous open surgery), beginning with impacts on immediate outcomes pertaining to the surgery itself. Relative to open surgeries, minimally invasive surgeries are less complex and involve fewer complementary services. For instance, our estimates suggest minimally invasive surgeries are substantially less likely to involve an overnight stay (a 2.7 p.p. or 2.9% reduction, on average) and are much more likely to be performed at an outpatient surgery center rather than an inpatient hospital (a 28.4 p.p. or 39.9% increase, on average). This reduced complexity may contribute to lower health care spending on the surgery date, with point estimates suggesting that, on average, health care spending on the surgery date is 14.6% lower for minimally invasive surgeries compared to analogous open surgeries.

We then turn to analyzing outcomes after the surgery—considering both cumulative impacts up to two years after surgery and impacts by quarter since surgery. Relative to open surgeries, minimally invasive surgeries, on average, involve \$5,274 or 30.4% less health care spending in the two years after surgery, reflecting reductions in both medical and prescription drug spending. The estimates indicate the reduction in health care spending in dollars is largest in the quarter immediately following surgery, though the reductions in spending are persistent and reflect similar or larger percent changes over time. We also analyze impacts on specific categories of health care that are commonly associated with post-surgical recovery including office visits and opioid use. In the two years following surgery, minimally invasive surgery leads to large reductions in both office visits (5.1 fewer visits or 63.6% of the mean) and opioid use (40.9 fewer days supplied or 85.3% of the mean). Further analysis illustrates minimally invasive surgery reduces opioid use immediately following surgery and reduces opioid dependence in the long run—with estimates indicating the

reduction in opioid use persists for at least two years after surgery and increases in percent terms with time since surgery. We also analyze impacts on “revision surgeries” (subsequent orthopedic surgery on the same body part to address the injury), as revision surgery is often required when issues remain unresolved after the initial surgery. Minimally invasive surgery is associated with a 7.5 p.p. reduction (a 43.9% decrease) in the likelihood of revision surgery.

Beyond analyzing impacts on health care utilization, we also analyze impacts on disability and associated social insurance costs. Relative to patients with open surgeries, those with minimally invasive surgery receive, on average, \$3,981—or 25.0%—less in subsequent cash disability benefits in the two years following surgery. Minimally invasive surgery is associated with 37.1 fewer days out of work receiving temporary income benefits after surgery—a 29.1% decrease relative to the open surgery mean. In addition, our estimates suggest minimally invasive surgery may improve recovery from the injury in the long term, with our estimates indicating minimally invasive surgery is, on average, associated with a 7.6 p.p. (or 11.9%) decrease in the likelihood of any permanent impairment and a 1.1 p.p. (or 30.4%) reduction in permanent impairment severity rating. Relative to open surgery, minimally invasive surgery is associated with a \$9,255 (or 27.8%) average decrease in total workers’ compensation costs in the two years following surgery, aggregating across health spending and cash disability benefits.

Heterogeneity analysis reveals the impacts of minimally invasive surgery seem to be universal—with estimates suggesting minimally invasive surgery leads to an across-the-board improvement in health and disability outcomes across all subgroups examined. Additionally, we conduct supplemental analysis illustrating the robustness of our main findings. For instance, we obtain similar estimates when focusing on planned surgeries, excluding surgeries performed on an emergency basis. We also show our findings are not driven by any particular surgery type, through illustrating we obtain similar estimates when excluding each surgery type one at a time. Moreover, we illustrate our findings are not driven by other correlated surgeon characteristics.

Next, we analyze trends in adoption of minimally invasive surgical techniques and interpret our primary findings in light of these trends. We document that the share of surgeries performed using minimally invasive techniques grew substantially over time, rising from 67.1% in 2008 to 73.2% in 2020. Combining this descriptive evidence with our baseline causal estimates, we assess the aggregate impact of the growing use of minimally invasive surgery. This analysis indicates that the increased adoption of minimally invasive surgery from 2008 to 2020 meaningfully improved aggregate post-surgical outcomes for injured workers, leading to declines in mean subsequent health care spending (1.9%), opioid use (5.3%), revision surgeries (3.1%), missed work days (1.8%), and permanent disability severity (1.9%). This improvement in outcomes substantially influenced overall trends in these outcomes over time, with our estimates suggesting diffusion of minimally invasive surgery can explain 15.0% of the reduction in post-surgical health care spending for these injured workers over this period. Additionally, we document vast geographic variation in the diffusion of minimally invasive surgery techniques, with estimates suggesting the 20% slowest-adopting areas have adoption rates roughly a decade behind the 20% fastest-adopting areas. We

conclude with back-of-the-envelope calculations considering the potential impact of policies aimed at accelerating the diffusion of minimally invasive techniques or aimed at narrowing geographic disparities in adoption.

Our study contributes to a broad interdisciplinary literature on the health impacts of innovation. A large medical literature documents immediate, short-run impacts of health care innovations on various treatment-specific measures (e.g., management of particular chronic conditions, adverse side effects, survey outcomes), using observational variation or small-scale clinical trials. Recent work in the economics literature uses quasi-experimental methods to analyze the impact of specific pharmaceutical innovations in the early 20th century in contributing to mortality and longevity trends over time. For example, some work has explored the invention of sulfa drugs (antibiotics used to treat a range of bacterial infections)—on mortality and life expectancy (Jayachandran, Lleras-Muney and Smith, 2010), women’s fertility (Bhalotra, Venkataramani and Walther, 2023), or later life outcomes among those with access to these treatments in childhood (Lazuka, 2020).⁸ In addition, an emerging literature has used quasi-experimental methods to analyze the impact of more recent pharmaceutical innovations on labor market trends and employment outcomes, including work on Cox-2 Inhibitor painkillers (Garthwaite, 2012; Bütkofer and Skira, 2018), mental health drugs (Bütkofer, Cronin and Skira, 2020; Shapiro, 2022; Biasi, Dahl and Moser, 2021), cancer drugs (Jeon and Pohl, 2019), and opioids (e.g., Beheshti (2023); Park and Powell (2021)). While the practice of medicine has evolved tremendously over the last few decades, little is known about the causal impacts of medical innovations that go beyond pharmaceuticals.

Our work makes several contributions to this literature. First, in contrast to prior work that has largely focused on pharmaceutical innovations, our study provides novel evidence on a major medical innovation. Unlike newly developed pharmaceuticals, medical innovations are typically not required to undergo clinical trials or demonstrate efficacy according to any metric. Beyond challenges in isolating plausibly exogenous variation to estimate causal impacts, estimating the impact of medical innovation is also challenging because it requires data on both outcomes and exposure to the innovation—which is often not universal as diffusion tends to be gradual. As a consequence, existing evidence on the causal impacts of medical innovation is very limited. Our study provides large-scale causal evidence on the impacts of an important medical innovation—the move from open surgery to minimally invasive surgery—which is arguably one of the most substantial surgical innovations in the past half century. Second, our study leverages unique linked administrative data to provide evidence on the impact of this major medical innovation on a broad range of outcomes—including health, health care use, labor supply, disability benefit receipt, and social insurance costs in the short, medium, and long runs. Third, we document novel evidence on diffusion patterns of this medical innovation, illustrating the dynamics of diffusion of minimally invasive surgery techniques across areas and across different types of surgeries. Combining these descriptive patterns with our estimates of the causal impact of minimally invasive surgery (relative to traditional open surgery), we illustrate how diffusion contributes to broader trends in outcomes

⁸Other recent work has examined impacts of antitoxins for Diphtheria (Ager, Hansen and Lin, 2024).

and explore how policy aimed at impacting diffusion patterns could potentially impact outcomes.

Additionally, our study complements a broader literature on social insurance programs covering risks related to health and disability. Prior work on disability and workers' compensation insurance has explored how program costs and individual outcomes are influenced by the existence of these programs (e.g., Maestas, Mullen and Strand (2013); Deshpande (2016)) or by various specific features of these programs—such as benefit generosity (e.g., Gelber et al. (2023); Cabral and Dillender (2024); Powell and Seabury (2018)) or the application/review process (e.g., Deshpande and Li (2019); Silver and Zhang (2022); Carey, Miller and Molitor (2022)). While disability often follows a major health shock, limited research has explored how treatment for disability-inducing health conditions impacts the trajectory of health, health care use, and disability going forward.⁹ And this can have important implications for the costs and design of related social insurance programs. Our paper extends this literature by providing novel evidence on the impact of a major medical innovation in the treatment of work-limiting injuries. Our findings illustrate that the major medical innovation we analyze—the move from open surgery to minimally invasive surgery—substantially improves the health and work capacity for those with musculoskeletal injuries. While innovation is often blamed for driving up health care costs, our findings illustrate that medical innovation can reduce subsequent health care spending and broader social insurance costs. Moreover, our estimates suggest medical innovation is a major determinant of social insurance costs for those with work-limiting injuries and measures of cost-effectiveness of these innovations should incorporate broader impacts on social insurance programs.

1 Background and Data

1.1 Setting: Orthopedic Surgery, Workplace Injuries, and Workers' Compensation Insurance

Our study analyzes impacts of minimally invasive surgery versus open surgery in the context of orthopedic surgeries on the musculoskeletal system. These surgeries are the most common type of surgery among prime-aged adults excluding obstetrics (McDermott and Liang, 2021*b*), and are typically done to address an injury to the musculoskeletal system. Many musculoskeletal injuries happen during the course of work, and our analysis focuses on orthopedic surgery addressing work-related injuries. In the U.S., workers' compensation insurance is the primary social insurance program that covers costs associated with these injuries.

Workers' compensation is a state-regulated insurance program that provides cash and health care benefits to employees who suffer workplace injuries.¹⁰ Differences in state programs exist, but

⁹Our study complements recent related work examining medical care received by injured workers, including work exploring the connection between the overall amount of medical spending for injured workers and their later labor market outcomes (Powell and Seabury, 2018) and work investigating how the duration of claiming income-replacement benefits is impacted by recreational marijuana laws (Abouk et al., 2023) or greater access to opioids (Savych, Neumark and Lea, 2019).

¹⁰While workers' compensation insurance covers both workplace injuries and illnesses due to occupational exposure,

the basic structure of workers' compensation insurance is similar across states. Employers purchase insurance policies or self-insure, and injured workers are eligible for benefits that are set by the state.

Workers' compensation insurance provides full coverage for health care related to workplace injuries, and injured workers have no out-of-pocket expenses for injury-related health care, regardless of their work status or receipt of cash disability benefits. Workers' compensation insurance is the first and only payer for all injury-related health care. Injured workers choose a "treating doctor"—typically a primary care doctor—who serves as their gatekeeper for both health care and cash benefits.¹¹ Treating doctors are responsible for coordinating and approving all non-emergency health care provided to injured workers and for making any necessary referrals to other providers, including surgeons and other specialists. Treating doctors can bill insurers for standard medical services they provide to injured workers, as well as for "case management services" related to overseeing workers' compensation insurance claims.¹² Typically, the first non-emergency visit for the injury establishes an injured worker's treating doctor. After establishing a treating doctor, changing treating doctors is very difficult; in Texas, such changes require substantial paperwork, a valid reason (e.g., the doctor retires, the patient moves), and approval by the Texas Department of Insurance.

While workers' compensation insurance covers a broad range of work-related health issues, the vast majority of claims are for musculoskeletal injuries. Orthopedic surgery is commonly used to address these injuries. In contrast to many other health care settings, injured workers receiving orthopedic surgery have very limited influence over which surgeon performs the procedure. Injured workers do not directly select surgeons. Specialty care is managed through a strict gatekeeper model, and treating doctors are responsible for referrals to surgeons. Moreover, several institutional features make it very unlikely that patients select treating doctors based on their referral patterns to surgeons. Information on treating doctor referral patterns is not easily available. And injured workers choose their treating doctor well before learning the full extent of their injury, whether they will need surgery, or which surgery they may need. The full extent of injury typically cannot be diagnosed through an initial examination and often requires a referral to and an assessment by a surgeon who often orders sequential diagnostic imaging (e.g., X-rays, MRIs, or CT scans) to visualize soft tissue and bone damage. In addition, there is often a delay in determining whether surgery is needed until the injury has stabilized, which can take weeks as the swelling subsides and functional limitations become clearer.

Beyond health care coverage, injured workers can receive two types of cash disability benefits through workers' compensation insurance: temporary income benefits and permanent impairment benefits. Claimants who have to miss work because of their injuries are eligible to receive temporary income benefits while they recover from their injuries. Temporary income benefits replace 70% of

nearly all claims are for workplace injuries.

¹¹In Texas, doctors of any specialty with an active medical license can be treating doctors, though the majority of treating doctors are general practitioners.

¹²Providers are paid based on a state-specified fee schedule or on contracts with insurers.

a claimant's average weekly wage, subject to minimum and maximum weekly benefit amounts, and begin after a waiting period. In Texas, injured workers are eligible for temporary income benefits after they miss at least seven days of work because of their injuries. Temporary income benefits continue until the earliest of the following: (i) injured workers return to work, (ii) their treating doctor determines they have reached "maximum medical improvement" (i.e., the point at which the injured worker's condition has stabilized and is unlikely to improve further, even with continued treatment), (iii) they reach the statutory limit for temporary income benefits, which in Texas is 104 weeks. In practice, it is uncommon for workers to receive temporary income benefits for the full two years. Temporary income benefit spells average 18 weeks in Texas, and beneficiaries typically return to work when temporary income benefits terminate, regardless of whether they have some degree of partial permanent impairment.¹³

After temporary income benefits end, workers can receive additional permanent impairment benefits if they have an ongoing (partial) permanent impairment. The degree of permanent impairment is assessed after the treating doctor determines the worker has reached maximum medical improvement. Treating doctors assign permanent impairment ratings based on the percentage of whole-body impairment caused by the injury. Permanent impairments in this population are typically minor and do not prevent return to work, with the mean claimant rated as 6% impaired (on a scale of 0% to 100%) among claimants with a non-zero permanent impairment rating. The worker's permanent impairment benefit is a fixed payment calculated based on the worker's impairment rating and prior average weekly wages. This benefit is unconditional, in that it is paid regardless of whether the claimant returns to work or their earnings upon returning to work.

1.2 Data Sources and Definitions

To examine the impact of minimally invasive surgeries in workers' compensation insurance, we compiled a novel dataset on surgeries for workplace injuries that combines multiple administrative data sources obtained through open records requests submitted to the Texas Department of Insurance and a unique dataset we constructed on surgeries that can be performed using either minimally invasive or open methods. Beyond our primary data sources, we also leverage supplemental information from various publicly available data sources and from data sources obtained through open records requests to other agencies.

The primary workers' compensation administrative data include all claims that occurred in Texas from January 2005 to July 2023 (TDI, 2023b). Data on workers' compensation claimants include health care data, which include all medical, pharmacy, and case management bills paid for by workers' compensation insurance. These data contain procedure codes (CPT codes), amount paid, diagnoses (ICD codes), date and place of service, and provider information, as well as a claim identifier that allows all health care to be linked back to the associated injury claim and to

¹³Leveraging linked administrative data from workers' compensation insurance and unemployment insurance earnings records, the Texas Department of Insurance documents that 76% of temporary income benefit recipients returned to work within six months of injury and 95% returned to work within three years of injury among those injured in 2011 (TDI, 2015).

other administrative data sources. These health care data are used to identify surgeries, surgery dates, and surgeons. The workers' compensation insurance data also include rich demographic and injury information about each claim, including claimant sex, birth date (month-year), injury date (month-year), and zip code. For claimants who receive cash benefits, the data contain information on the type of cash benefits received, total benefits received, prior average weekly wages, and benefit start and end dates (TDI, 2023a). Our primary analysis focuses on health care and cash benefit outcomes using two years of information after surgeries. Throughout, all monetary values are adjusted to December 2020 dollars using the Consumer Price Index (BLS, 2025).

Our analysis sample includes surgeries occurring from June 2007 to April 2021 for which we can identify the surgeon. We focus on surgeries that happened from June 2007 onward because we use National Provider Identifiers (NPI) to identify surgeons, and NPIs became effective beginning in May 2007. We focus on surgeries happening before May 2021 to ensure that we have two years of post-surgery information for all surgeries, and we focus on surgeries performed within 360 days of the claim start date. For claimants with multiple surgeries, we focus on the earliest surgery because subsequent surgeries and health care use are endogenous to the first surgery performed.

For basic information on surgeons, including sex and taxonomy code, we draw on data from the Centers for Medicare & Medicaid Services' (CMS) NPI registry (CMS, 2024). We supplement these data with additional information on surgeon characteristics from the Medicare Physician Compare File (CMS, 2025) and the Texas Medical Board website (TMB, 2025).

We aim to estimate the impact of minimally invasive surgery techniques (relative to conventional open surgical techniques) for orthopedic surgery. Our main analysis focuses on "target surgeries"—which we define as orthopedic surgeries with procedure codes that reflect that these surgeries can be performed using either open or minimally invasive techniques, excluding procedures that are purely diagnostic. We compiled a novel comprehensive dataset cataloging all target surgeries following several steps. We first identified all procedure codes for orthopedic surgeries that involve the use of minimally invasive methods facilitated by scopes (i.e., arthroscopic surgery). We then grouped these procedure codes into "surgery types"—that reflect the nature of the surgery and the body part on which the surgery was conducted (e.g., shoulder rotator cuff repair, knee meniscus surgery). For each surgery type, we then identified all procedure codes for analogous open surgeries through consulting numerous medical studies and coding references. Appendix Section A provides further details.

To facilitate our analysis, we define "target encounters" as dates on which a given individual has a target surgery, focusing on target surgeries that were the primary procedure performed on that date (defined as the procedure with the highest charges on that date). Our final sample includes 93,350 target encounters, where these surgeries were performed by 978 surgeons. We code an encounter as "minimally invasive" if the associated target surgery employed minimally invasive surgery techniques and as "open" otherwise. Appendix Section B provides more detail on these definitions.

1.3 Descriptive Statistics

Table 1 lists the most common target surgeries in our data, along with basic information including the share of these surgeries that are minimally invasive over the analysis period and some basic demographic information on patients receiving these surgeries. The most common target surgeries are knee meniscectomy, shoulder rotator cuff repair, and knee ACL/PCL reconstruction, which collectively account for approximately half of target surgeries. The next most common target surgeries include shoulder subacromial decompression, wrist/forearm fracture fixation, and shoulder biceps tenodesis. It is important to note that minimally invasive surgical methods were developed at different times for different types of surgeries, and hence the mean share of surgeries that are minimally invasive differs dramatically across common target surgeries over this time frame. For instance, over the sample period, 63.1% of shoulder rotator cuff repair surgeries are minimally invasive, whereas only 8.2% of wrist/forearm fracture fixation surgeries are minimally invasive.

Table 2 summarizes patients with target surgeries included in our analysis. Column (1) describes the full sample, while columns (2) and (3) describe the subsets of patients with open and minimally invasive surgeries, respectively. Panel A summarizes basic characteristics. Seventy percent of patients are male and the mean age is 46.8. The mean age and share male are similar among patients with open and minimally invasive surgery, and these basic demographics broadly align with those in the overall population of injured workers. Overall, 70.1% of surgeries are minimally invasive. Target surgeries span a range of body parts, with the most common being knee, shoulder, wrist/forearm, and hand. The prevalence of minimally invasive techniques compared to open techniques varies across surgeries and body parts, with minimally invasive techniques relatively more common among surgeries on the knee and shoulder.

Table 2 Panel B summarizes pre-surgery characteristics among patients with target surgeries included in our analysis. We note that the observed period before surgery is limited to the time from injury to surgery, and health care is limited to injury-related health care. On average, 101 days pass between a worker's injury and the target surgery, with only 1.4% of surgeries taking place on the first day the injury was treated.¹⁴ Among injured workers in our sample, 31.4% first received treatment for their injury through the Emergency Department (ED), and mean health care spending on the first day the injury is treated is \$644. For workers with more than two weeks between injury and surgery, we also summarize total pre-surgery health care use over the first two weeks of the claim.¹⁵ During the first two weeks after injury, injured workers have, on average, \$1,237 in health care spending, 1.8 office visits, and 0.9 physical therapy visits to treat their injury. In the first two weeks after injury, 25.1% of injured workers fill an opioid prescription and the mean days supplied of opioids is 2.9.

¹⁴Figure 8 illustrates our findings are robust when dropping surgeries potentially done on an emergency basis—these first-day surgeries and surgeries on the same day as an Emergency Department visit.

¹⁵For these descriptive statistics, we focus on the 87.2% of claims with at least 17 days between the claim start date and the surgery. These variables measure health care over the first 14 days since claim start. Because we aim for these measures to capture pre-surgery health care spending, we construct these measures for claimants with at least 17 days between claim start and surgery—ensuring a minimum of three days between this window and the surgery—to exclude health care directly related to the surgery itself.

Comparing columns (2) and (3), we see that there are notable differences in pre-surgery characteristics between patients receiving open and minimally invasive surgery. For example, patients with minimally invasive surgery are 12.2 p.p. (30.6%) less likely to have received initial treatment for their injuries in the ED, have \$279 (33.1%) lower first-day health care spending for their injuries, and are 4.6 p.p. (16.1%) less likely to have any opioid prescriptions in the first two weeks their injuries are treated. These differences are large, and further analysis confirms they are statistically significant (see Figure 3). Overall, these patterns in baseline characteristics suggest that, on average, claimants receiving minimally invasive surgery have less serious injuries compared to those receiving open surgery.

2 Empirical Strategy

2.1 Overview

Whether a patient receives open or minimally invasive surgery after an injury can depend on a number of factors—including characteristics of the patient or the surgery. Some of these factors may have independent effects on surgery and recovery outcomes. For example, emergency surgeries may be more likely to be open and may also be more likely to have worse outcomes than non-emergency surgeries, regardless of surgical method (Ceresoli et al., 2022). Similarly, surgeries with complications developing mid-surgery may convert to being open from minimally invasive, and the complications that necessitate the open surgery could also increase recovery times. In addition, certain patient comorbidities or anatomical features could make patients a better candidate for minimally invasive surgery or open surgery and may also be associated with differential surgery recovery regardless of surgical method (Rosenberg, 2016). Because of these confounders, OLS regressions of outcomes on an indicator variable for whether a patient has minimally invasive surgery would yield biased estimates of the impact of minimally invasive surgery (relative to open surgery)—and instead would capture a combination of the causal impact of receiving minimally invasive surgery and any differences in patient or surgery characteristics across surgical methods.

To overcome the endogeneity of the surgical method, our research design isolates variation in whether a patient receives the minimally invasive version of a surgery that comes from the surgeon’s propensity to use minimally invasive methods. Surgeons vary in their propensity to perform minimally invasive surgery for a variety of reasons, including differences in surgeon preferences, in exposure to minimally invasive methods, and in when (and how extensively) surgeons choose to integrate minimally invasive techniques in their practice. These differing propensities across surgeons mean patients can receive minimally invasive surgery instead of open surgery because of the minimally invasive intensity of the surgeon the patient happens to see and for reasons unrelated to baseline patient characteristics.

Our empirical strategy, which we describe in detail below, aims to estimate the impact of receiving minimally invasive surgery (rather than open surgery) leveraging variation in surgical method that arises from surgeon tendencies rather than from patient or surgery characteristics.

Specifically, we use an instrumental variables research design where we instrument for whether a given patient receives minimally invasive surgery using their surgeon's propensity to perform minimally invasive surgery—where we adopt a leave-one-out approach to measure surgeon propensities to avoid issues with small sample correlation between the surgical method used for a given patient and the measure of the surgeon propensities.

2.2 Econometric Model

Our baseline specification aims to estimate the impact of receiving a given surgery using minimally invasive techniques rather than conventional open surgery. Because whether an individual receives the minimally invasive or open version of a surgery may depend on individual characteristics and circumstances, we use an instrumental variables strategy leveraging variation across surgeons in their general propensity to use minimally invasive techniques. Specifically, we estimate the following instrumental variables specification:

$$Y_i = \delta Minimally_Invasive_i + X_i \boldsymbol{\theta} + \omega_{s(i)t(i)} + \epsilon_i \quad (1)$$

$$Minimally_Invasive_i = \zeta z_{id(i)} + X_i \boldsymbol{\beta} + \nu_{s(i)t(i)} + e_i, \quad (2)$$

where i represents an individual, $d(i)$ the surgeon associated with individual i , $s(i)$ the surgery type individual i received (e.g., knee ACL repair, shoulder rotator cuff repair, etc.), and $t(i)$ the year individual i had surgery. Equation (2) is the first stage equation relating the potentially endogenous indicator for whether a surgery was minimally invasive ($Minimally_Invasive_i$) to the surgeon minimally invasive intensity instrument ($z_{id(i)}$), fixed effects for surgery type by year ($\nu_{s(i)t(i)}$), and additional controls (X_i) for demographics (individual age and sex) and for the medical market in which the individual resides (fixed effects for the Hospital Referral Region as defined by the Dartmouth Atlas (DAP, 2021)). Equation (1) models the relationship between outcomes of interest (Y_i) and the surgery being minimally invasive ($Minimally_Invasive_i$), including surgery type by year fixed effects ($\omega_{s(i)t(i)}$) and the same additional controls (X_i). We measure outcomes at different time intervals since the surgery was performed. Standard errors are clustered at the surgeon level.

The surgeon intensity instrument we construct relies on the idea that a surgeon's overall propensity to use minimally invasive surgery techniques can be measured by a surgeon's average propensity to do minimally invasive surgery among all other surgeries, averaging over surgeries leaving out the surgery on individual i . Because the composition of surgeries varies across surgeons, we use a UJIVE (Unbiased Jackknife Instrumental Variables Estimator) approach to construct an instrument that isolates variation across surgeons in their leave-out propensity to use minimally invasive techniques, controlling for the mix of surgeries they perform through observed characteristics of these surgeries. We use this UJIVE approach as it is generally preferred to a traditional leave-one-out JIVE (Jackknife Instrumental Variables Estimator) approach in settings with covariates (Kolesár, 2013). Specifically, for each individual i , we first estimate the following two equations

using a leave-out sample—excluding the index individual i —denoted by the subscript $-i$:

$$\text{Minimally_Invasive}_{-i} = \mathbf{X}_{-i}\boldsymbol{\alpha} + \gamma_{s(-i)t(-i)} + \mu_{-i} \quad (3)$$

$$\text{Minimally_Invasive}_{-i} = \mathbf{X}_{-i}\boldsymbol{\pi} + \phi_{s(-i)t(-i)} + \kappa_{d(-i)} + v_{-i}, \quad (4)$$

where both equations include surgery type by year fixed effects ($\gamma_{s(-i)t(-i)}$; $\phi_{s(-i)t(-i)}$) and additional controls (\mathbf{X}_{-i}) as in Equations (1) and (2) above. Equation (4) additionally includes surgeon fixed effects ($\kappa_{d(-i)}$). We then obtain the surgeon intensity instrument for individual i by subtracting the fitted value of Equation (3) from the fitted value of Equation (4), where each fitted value is separately calculated using the estimated coefficients for the characteristics associated with individual i in each equation: $z_{id(i)} \equiv (\mathbf{X}_i\hat{\boldsymbol{\pi}} + \hat{\phi}_{s(i)t(i)} + \hat{\kappa}_{d(i)}) - (\mathbf{X}_i\hat{\boldsymbol{\alpha}} + \hat{\gamma}_{s(i)t(i)})$. Intuitively, this instrument captures the surgeon’s propensity to use minimally invasive methods among surgeries on the surgeon’s other patients, accounting for observed compositional differences in patient and surgery characteristics such as location, surgery type, time, and demographics.

2.3 Identifying Variation

Figure 1 displays a histogram of $z_{id(i)}$. There is substantial residual variation in $z_{id(i)}$ with an interquartile range of 15.0 p.p. and an interdecile range of 28.4 p.p. This wide range suggests there is considerable variation in the use of minimally invasive surgery among similar patients. Figure 2 Panel A shows a binned mean residual plot, relating $\text{Minimally_Invasive}_i$ —residualized using the baseline IV controls—to $z_{id(i)}$. This figure indicates the likelihood an individual receives the minimally invasive version of a surgery strongly increases in the surgeon’s minimally invasive intensity based on the surgeon’s other patients ($z_{id(i)}$), the magnitude of this relationship is approximately one-for-one, and this relationship is roughly linear. This provides strong evidence supporting the relevance of the instrument in predicting the likelihood a patient has minimally invasive surgery.

For $z_{id(i)}$ to serve as a valid instrument for identifying causal impacts, it must also satisfy an independence assumption (that $z_{id(i)}$ is unrelated to other determinants of our outcomes of interest, Y_i , conditional on the included controls) and an exclusion restriction (that $z_{id(i)}$ only impacts outcomes of interest, Y_i , through impacting the likelihood a surgery is minimally invasive, $\text{Minimally_Invasive}_i$, conditional on the included controls). Institutional features—such as the strict gatekeeper model for workers’ compensation covered health care and the limited scope for patients to influence which surgeon performs their surgery—support the plausibility of the independence assumption. Moreover, we empirically assess the plausibility of the independence assumption through two related analyses. First, we analyze the relationship between our instrument and the predicted likelihood of minimally invasive surgery based on baseline patient and injury characteristics. To estimate the predicted likelihood of minimally invasive surgery, we use data on a wide range of baseline (pre-surgery) characteristics including proxies for the severity of the injury (an indicator for whether the claim originated with an ED visit, health spending on the first day of the claim, an indicator for surgery on the first day of the claim), time between injury and surgery,

and measures of health care utilization in the first two weeks of the claim among claimants with sufficient time between injury and surgery.¹⁶ Figure 2 Panel B displays a binned mean residual plot relating residualized $\text{predicted } \textit{Minimally_Invasive}_i$ to $z_{id(i)}$.¹⁷ In contrast to the patterns seen in Figure 2 Panel A relating the actual surgical method to the instrument, Figure 2 Panel B indicates there is no relationship between predicted $\text{Minimally_Invasive}_i$ based on baseline characteristics and $z_{id(i)}$ —consistent with the independence assumption.

Second, we examine the relationship between our instrument and each pre-surgery characteristic one-by-one. Figure 3 displays estimates of the coefficient on $z_{id(i)}$ from separate regressions relating pre-surgery characteristics to the instrument, including the baseline IV controls. For comparison, this figure also presents estimates from OLS regressions of baseline characteristics on $\text{Minimally_Invasive}_i$, capturing observational patterns.¹⁸ There are two key takeaways from this analysis. First, the coefficients on the instrument are small and statistically indistinguishable from zero for all pre-surgery characteristics. Moreover, when estimating a reverse regression relating the instrument to all pre-surgery characteristics simultaneously, we cannot reject these characteristics are jointly unrelated to the instrument, with a joint F-stat of 1.73. This suggests the identifying variation is unrelated to baseline characteristics, consistent with the independence assumption. Second, in contrast, the coefficients on $\text{Minimally_Invasive}_i$ in the OLS regressions are often large and nearly always statistically distinguishable from zero. This highlights the importance of using our research design to isolate plausibly exogenous variation in the use of minimally invasive surgical techniques.

Beyond the independence assumption, the exclusion restriction requires that the instrument only impact outcomes through the causal impact on the likelihood of minimally invasive surgery. One concern in this setting is that other surgeon characteristics could be correlated with minimally invasive surgery intensity, and this could be a violation of the exclusion restriction if these characteristics are also independently related to outcomes. We explore this possibility in Section 3.3 through two supplemental analyses. First, we document the association between our instrument and observable surgeon characteristics, such as sex, education, and experience. This analysis reveals that two surgeon characteristics—sex and years of experience—are correlated with our instrument, though the magnitudes of these correlations are modest. Second, we investigate the robustness of our findings when controlling for observed surgeon characteristics. Our estimates are nearly identical when including additional controls for surgeon characteristics, either individually or all together. Collectively, these analyses suggest that correlated surgeon characteristics do not explain our findings—providing support for the exclusion restriction.

We note that if treatment effects are not constant, a further assumption is needed to causally interpret the instrumental variables estimates: average monotonicity. In this setting, the aver-

¹⁶Appendix Section B contains details on how these measures are calculated.

¹⁷As in Figure 2 Panel A, the dependent variable is residualized by the baseline IV controls.

¹⁸Appendix Table A1 displays the corresponding estimates, along with their standard errors and p-values. Note the first stage evidence in Figure 2 Panel A shows a one-for-one relationship between $\text{Minimally_Invasive}_i$ and $z_{id(i)}$. Thus, while Figure 3 shows two sets of analyses with different key independent variables ($\text{Minimally_Invasive}_i$ and $z_{id(i)}$), it may be reasonable to compare magnitudes across these analyses.

age monotonicity condition means that having a surgeon with higher $z_{id(i)}$ weakly increases the likelihood that the patient receives minimally invasive surgery. Under this average monotonicity condition, the estimates described above represent a weighted average treatment effect with appropriate LATE weights. A common test for average monotonicity is to examine whether the key coefficient in the first stage regression is consistently positive across subgroups (Frandsen, Lefgren and Leslie, 2023). Appendix Table A2 presents first stage estimates relating $Minimally_Invasive_i$ to $z_{id(i)}$ across several subgroups defined by pre-surgery patient characteristics: age, sex, and health care use. Across all subgroups, the coefficient relating $Minimally_Invasive_i$ to $z_{id(i)}$ is positive and statistically significant, providing support for the average monotonicity assumption.

Because our main analysis focuses on patients who received the target surgeries, a natural question to ask is whether patients select into receiving surgery based on surgeon propensities to use minimally invasive methods. We note that selection of this type would only bias our estimates if this selection were related to patient level determinants of our outcomes of interest, and hence the evidence discussed above on balance in baseline characteristics is reassuring that such selection (if present) may not interfere with identification. Nevertheless, we directly explore the possibility of selection into surgery through supplemental analyses. Specifically, we consider a broader sample of individuals potentially eligible to have surgery—all patients in the data who ever had an office visit with an orthopedic surgeon in our sample. Typically, patients have an office visit with their surgeon prior to surgery, but not all office visits with surgeons result in later surgery (because, for example, surgery is not recommended as treatment or other factors lead patients not to follow through with surgery, etc.). Within this broader sample, we predict the likelihood a claimant will have any target surgery after an office visit with an orthopedic surgeon, by regressing an indicator of having any subsequent surgery on patient demographics (age, sex), medical market fixed effects (HRR), and diagnoses by year fixed effects based on diagnoses at the initial office visit with an orthopedic surgeon. We interpret fitted values from this regression as the ex ante predicted probability of surgery, and analyze whether this predicted probability varies with our instrument conditional on the controls in the IV strategy. See Appendix Section C for further details. Appendix Figure A1 reports these estimates along with an associated plot relating the residualized predicted probability of surgery to $z_{id(i)}$, where the predicted probability of surgery is residualized on the IV controls. This analysis suggests the predicted probability of surgery is not related to our instrument $z_{id(i)}$ —and thus the ex ante likelihood of surgery is not related to our identifying variation in surgical method.

3 Impact of Minimally Invasive Surgery

This section presents estimates of the impacts of minimally invasive surgery relative to open surgery. We begin by presenting the baseline estimates of the impacts of minimally invasive surgery—estimates of both the cumulative impacts on outcomes and the dynamics of these impacts. We then analyze heterogeneity in these impacts and the robustness of the findings.

3.1 Main Estimates

Table 3 reports the main IV estimates focusing on the key coefficient on $Minimally_Invasive_i$ from Equation (1). Each row represents results from a separate regression for the indicated dependent variable. Columns (1) and (2) report the mean and standard deviation of the dependent variable among those receiving open surgery, whereas the remaining columns report the coefficient estimate on $Minimally_Invasive_i$, the associated standard error and p-value, and the implied impact as a percent to the mean among those with open surgery. Figures 4 through 6 and Appendix Figures A2 and A3 plot analogous estimates by quarter since surgery to illustrate the dynamics of the cumulative impacts on health care, disability, and social insurance outcomes reported in Table 3.

Surgery Outcomes Table 3 Panel A describes impacts on surgery outcomes—outcomes describing the surgery encounter itself. This analysis explores features that describe the complexity of the surgery such as the length of stay associated with the surgery and the location of the surgery. Minimally invasive surgeries are 2.7 p.p (or 2.9%) more likely to be a “day surgery” (p-value 0.026)—a surgery where there is no overnight stay required. Relative to the analogous open surgeries, minimally invasive surgeries are 28.4 p.p. (39.9%) more likely to be performed in an outpatient surgery center (p-value 0.002) and 9.6 p.p. (57.3%) less likely to be performed at an inpatient hospital (p-value 0.041). These estimates suggest that minimally invasive surgeries are less complex—they require less time and are more likely to be performed in settings that typically require fewer resources than analogous open surgeries.

We also investigate impacts on total health care spending on the surgery date and spending on the target surgery procedure in particular. While these estimates are not statistically distinguishable from zero, the point estimates suggest that minimally invasive surgery is associated with \$1,078 (14.6%) less total health care spending on the surgery date and somewhat less (\$231 or 7.7%) spending on the target procedure.

Health Care Outcomes Table 3 Panel B describes cumulative impacts on health care outcomes in the two years following surgery (including the surgery encounter itself), while Figures 4 and 5 and Appendix Figure A2 explore the dynamics of these impacts by quarter since surgery. Compared to the analogous open surgeries, minimally invasive surgeries, on average, involve \$5,274 less total health care spending in the two years after the surgery (p-value 0.025); this impact is large and represents a 30.4% reduction relative to the mean among injured workers with open surgery. Decomposing this difference, minimally invasive surgeries are associated with \$4,553 less medical spending (p-value 0.033) and \$720 less prescription drug spending (p-value 0.011). Figure 4 Panels (a) through (c) explore the dynamics of these impacts. While the reduction in health care spending—both aggregate and by category—is largest in the first few quarters following surgery, we see that the reductions in spending are persistent and reflect similar or larger percent changes as time passes after surgery.

In addition to analyzing health care spending, we examine impacts on health care services

particularly relevant for post-surgical recovery including office visits, physical therapy visits, and prescription pain medication—in particular, opioids. Based on the estimates, minimally invasive surgery, on average, involves 5.1 fewer office visits (63.6%) in the two years following surgery (p -value 0.003) and is associated with \$505 (54.8%) less spending on office visits (p -value 0.004). We find suggestive evidence of a reduction in physical therapy utilization for those with minimally invasive surgery, with point estimates suggesting a \$1,353 decline in physical therapy spending over the two years after surgery (p -value 0.064). Figure 5 Panels (a) through (d) report impacts by quarter relative to surgery. These results indicate that the impact of minimally invasive surgery on office visits is largest in the quarter immediately after the surgery, though the impacts remain negative and statistically significantly distinguishable from zero for each quarter in the two years after surgeries. While minimally invasive surgery does not have a clear impact on physical therapy utilization immediately following surgery, the estimates suggest minimally invasive surgery reduces the duration patients receive physical therapy after surgery—as the estimates indicate minimally invasive surgery is associated with significant reductions in physical therapy utilization months after the surgery.

Opioids are commonly prescribed to ease pain during recovery from surgery and to manage pain from musculoskeletal injuries more generally. Motivated by this, we examine impacts on opioid use. Although there is no strong evidence that minimally invasive surgery influences whether patients use any opioids in the two years after surgery, patients undergoing minimally invasive surgery experience large reductions in overall opioid use on the intensive margin, measured as either total opioid days supplied (i.e., the number of days opioids are intended to last based on the patient's filled prescriptions) or the total number of distinct opioid prescriptions filled. Relative to those with an analogous open surgery, those with minimally invasive surgery have 40.9 (85.3%) fewer days supplied of opioids (p -value 0.005) and 1.4 (38.9%) fewer distinct prescriptions for opioids (p -value 0.065) in the two years following surgery. Figure 5 Panels (e) and (f) and Appendix Figure A2 Panel (a) display the dynamics of these impacts. While lower opioid use is observed starting the quarter of the surgery, the implied percent reduction in opioid use increases as time passes after surgery and remains statistically significant two years after surgery. For instance, in the eighth quarter after surgery, the estimates indicate minimally invasive surgery is associated with a 4.3 p.p. (84.5%) decline in the likelihood of any opioid prescription (p -value 0.008), 2.5 (83.3%) fewer days supplied (p -value 0.013), and 0.11 (76.6%) fewer prescriptions (p -value 0.014). This long-run reduction in opioid use is substantial and suggests minimally invasive surgery may meaningfully reduce long-term opioid dependence compared to open surgery.

In addition, we examine whether there are impacts on outcomes that may indicate surgical complications. Specifically, we investigate impacts on Emergency Department (ED) visits and subsequent surgeries to address the injury. We find no evidence that minimally invasive surgery impacts subsequent ED visits or ED spending, either for the full two-year post-surgery window in Table 3 or when considering the dynamics of the impacts in Appendix Figure A2 Panels (b) and (c).

Treating musculoskeletal injuries is complex. If an initial surgery is not fully successful in

addressing the injury, a “revision surgery”—subsequent surgery on the same body part to address the injury—may be needed, and revision surgeries are fairly common, with 17.0% of injured workers in our sample receiving one after an initial open surgery. Our analysis suggests minimally invasive surgery is associated with fewer revision surgeries. Relative to those with open surgery, workers receiving minimally invasive surgery, on average, have a 7.5 p.p. (43.9%) lower likelihood of any revision surgery (*p*-value 0.038) and receive 0.1 (49.5%) fewer revision surgeries in the two years following the initial surgery (*p*-value 0.027). Fewer revision surgeries contribute to lower overall post-surgery health care spending among those with minimally invasive surgery, with the estimates indicating minimally invasive surgery is associated with \$405—or 62.8%—less health care spending on revision surgeries in the two years following surgery (*p*-value 0.061). Appendix Figure A2 Panels (d) through (f) consider dynamics of these impacts. The estimates indicate that, relative to open surgeries, minimally invasive surgeries reduce rates of revision surgeries in months following surgery, with effects that become smaller in magnitude over time.

Disability and Social Insurance Outcomes Table 3 Panel C reports impacts on outcomes related to disability and social insurance in the two years following surgery. Figure 6 and Appendix Figure A3 display analogous estimates of the impacts by quarter since surgery. We begin by examining impacts on total cash disability benefits received through workers’ compensation insurance. Compared to open surgery, minimally invasive surgery is associated with \$3,981 less in cash disability benefits over the subsequent two years (*p*-value 0.023), which is a 25.0% reduction relative to the mean subsequent cash disability benefits received by those with analogous open surgeries. The estimated reduction in cash disability benefits for those with minimally invasive surgery is driven by differences in both temporary income benefits and permanent impairment benefits. Overall, roughly two thirds of the total reduction in cash disability benefits associated with minimally invasive surgery is accounted for by temporary income benefits, while the remaining third is due to permanent impairment benefits. Figure 6 Panel (a) displays the dynamics of the impact on total cash disability benefits. These estimates indicate minimally invasive surgery reduces cash disability benefits in the quarter following surgery and this reduction persists for months after surgery and increases over time since surgery in percent terms.

We turn to investigating impacts on workers’ compensation benefits in greater detail to understand how minimally invasive surgery impacts injury recovery, return to work, and permanent disability. Relative to open surgery, minimally invasive surgery is associated with 37.1 fewer missed days of work while receiving temporary income benefits—a 29.1% reduction relative to those with open surgery (*p*-value 0.004). Moreover, the estimates suggest that minimally invasive surgery decreases the likelihood of having any compensated time off of work by 5.0 p.p.—a 6.3% decrease over the mean of 79.9% among workers with open surgery (*p*-value 0.045). Figure 6 Panel (b) displays the impact on days out of work receiving temporary income benefits by quarter, and the results indicate the impact is largest in the first two quarters after surgery, with effects halving by one year after surgery and slowly converging to zero by two years after surgery.

Additionally, we examine whether minimally invasive surgery improves recovery from the injury in the long term—and hence ongoing permanent impairments among workers. The estimates indicate that minimally invasive surgery results in a 7.6 p.p. decrease in the likelihood of any permanent impairment, which is an 11.9% decrease relative to the mean (p-value 0.024). In addition, minimally invasive surgery is, on average, associated with a 1.1 p.p. reduction in permanent impairment severity among injured workers—or a 30.4% reduction relative to the mean permanent impairment severity rating among workers receiving an analogous open surgery (p-value 0.001). Note permanent impairments are only rated and compensated after the worker has completed temporary income benefits, and most workers are out of work receiving temporary income benefits directly after the surgery. Thus, impacts on permanent impairment benefits may only appear months after the surgery. Consistent with this expected pattern, Figure 6 Panel (c) illustrates that impacts on permanent impairment benefits appear in the third quarter after surgery and persist until two years after surgery.

Lastly, we examine impacts of minimally invasive surgery on total subsequent workers' compensation insurance costs—aggregating subsequent health care spending and cash disability benefits. Our estimates indicate that those with minimally invasive surgery have \$9,255 lower total subsequent workers' compensation insurance costs in the two years following surgery—27.8% less than the mean among those with open surgery (p-value 0.005). Figure 6 Panel (d) displays the dynamic impacts on total subsequent workers' compensation insurance costs. The reduction on total workers' compensation costs begins in the first quarter after surgery and grows in percent terms as time increases since surgery. In the eighth quarter after surgery, total workers' compensation costs are \$482 lower—66.9% of the mean—among patients undergoing minimally invasive surgery (p-value 0.005).

3.2 Heterogeneity

We explore heterogeneity in the impact of minimally invasive surgery by pre-surgery patient characteristics, including demographics (sex and age) and characteristics of the injury (e.g., severity proxies). Figure 7 plots the key coefficient estimates on $Minimally_Invasive_i$ —along with implied 95% confidence intervals—obtained when re-estimating the baseline IV specification for the indicated subgroups. Each panel reports estimated impacts for the indicated dependent variable: total health care spending (Panel (a)), medical spending (Panel (b)), prescription drug spending (Panel (c)), total cash benefits (Panel (d)), days of temporary income benefits (Panel (e)), permanent impairment benefits (Panel (f)), and total workers' compensation costs (Panel (g)). Appendix Tables A3 and A4 report the underlying estimates, standard errors, and percent impacts relative to the subgroup control mean.

There are a few patterns worth noting. First, the impacts appear universal—across all subgroups and outcomes. For all groups, minimally invasive surgery leads to decreases in subsequent health care spending—both medical and prescription drug spending—and minimally invasive surgery leads individuals to return to work faster, reduces the severity of partial permanent disabilities,

and reduces overall workers' compensation insurance costs. In other words, the evidence suggests minimally invasive surgery (relative to open surgery) improves health and reduces disability severity across the board. Second, patterns in the point estimates suggest that minimally invasive surgery may impact subsequent health spending more for some subgroups than others. For instance, the patterns in the estimates suggest that minimally invasive surgery may decrease subsequent health spending more for claimants below the median age, who are female, or with more severe injuries (e.g., those with higher first day health care spending or those with first treatment for their injury in an ED).¹⁹ We note that this suggestive evidence of heterogeneity is limited to health care spending, as there is no evidence of meaningful heterogeneity in the impact of minimally invasive surgery on disability outcomes (e.g., days out of work, permanent impairments, or cash disability benefits).

3.3 Robustness

Next, we investigate the robustness of our findings. Specifically, we consider alternative specifications varying the sample definition or including further controls. For simplicity, this analysis focuses on three primary dependent variables—total health care spending, total cash benefits, and total workers' compensation insurance costs—though the findings are similarly robust across all outcomes analyzed.

Sample Definition We investigate the robustness of our results when varying the sample definition. First, we consider robustness when excluding emergency surgeries. Few surgeries in our sample are done on an emergency basis—with only 2.5% of surgeries performed on the same day as an ED visit or on the first day an injury was treated. Because patients with these surgeries may be fundamentally different, we investigate the robustness of the results to excluding them. Figure 8 plots the key coefficient estimates and 95% confidence intervals for *Minimally_Invasive_i*, comparing estimates from the baseline sample to those in the restricted sample excluding emergency surgeries. Across the outcomes analyzed, the estimates are nearly identical when excluding patients with emergency surgeries.

Second, we investigate whether our results are driven by any one type of surgery. To consider this, we re-estimate our main specification excluding each surgery type one at a time. Appendix Figure A4 plots the estimates of this exercise, where the baseline estimates are included in the top row for reference. Across these regressions, the estimates are statistically distinguishable from zero and in the same range. The similarity of the estimates across these regressions indicates that our findings are not driven by one particular surgery type.

¹⁹We characterize these differences as suggestive evidence of heterogeneity as some of these differences in impacts are not statistically significant at conventional levels. For instance, reductions in health care spending are \$2,641 larger for women (p-value 0.016), \$5,333 larger for those with below median age (p-value < 0.001), \$1,914 larger for those with first treatment for their injury in the ED (p-value 0.090), and \$1,863 larger for those with above median first day health care spending on their injury (p-value 0.112). See Appendix Table A4 for the full set of p-values formally testing for differences in impacts across subgroups.

Other Surgeon Characteristics Given our research design, one concern is that other surgeon characteristics could be correlated with the instrument and could contribute to our findings. We conduct two complementary related analyses to assess this concern. First, we document the association between our instrument and observable surgeon characteristics—such as sex, education, and experience. Second, we investigate the robustness of our findings when controlling for observed surgeon characteristics.

Appendix Figure A5 displays binned mean residual plots relating residualized surgeon characteristics to our instrument, where surgeon characteristics are residualized by our IV controls. We consider several characteristics including sex and education (an indicator for having graduated from a top 25 medical school, credential). In addition, we examine surgeon experience—years since medical school graduation and volume of target surgeries performed (in our data)—where these measures are specific to the surgery and capture experience accrued before the surgery date. Appendix Figure A5 suggests no relationship between the likelihood that surgeons perform minimally invasive surgeries and surgeon education or volume. Surgeon sex and years of experience are associated with the propensity to use minimally invasive surgery techniques, though the magnitude of this association is modest—with a one standard deviation increase in the instrument ($z_{id(i)}$) being associated with a 0.88 p.p. decrease in the likelihood the surgeon is female and 1.9 fewer years of experience.

Because some surgeon characteristics are correlated with our instrument, we investigate the robustness of our findings when controlling for observed surgeon characteristics. Specifically, we re-estimate the main IV specification including observable surgeon characteristics as additional controls—both individually and simultaneously. Figure 9 displays the coefficient estimates and 95% confidence intervals for $Minimally_Invasive_i$, comparing estimates from the baseline specification to those from specifications with additional controls for the indicated surgeon characteristics. The estimated impacts of minimally invasive surgery are nearly identical when including these additional controls. Overall, this evidence suggests that our findings are not driven by correlated surgeon characteristics.

4 Diffusion of Innovation

This section presents descriptive evidence on the diffusion of minimally invasive surgery over time. We then combine this descriptive evidence with our estimates of the causal impact of minimally invasive surgery to assess the role of this surgical innovation in contributing to trends in outcomes over time and the potential impacts of policies aimed at accelerating the adoption of surgical innovation.

4.1 Descriptive Evidence

We begin by providing descriptive evidence of trends in minimally invasive surgery over time based on our data. This analysis focuses on a period spanning 13 years from 2008 to 2020, the years

of coverage for the data on the key measures we analyze. Figure 10 reports trends in the use of minimally invasive techniques among target surgeries accounting for the composition of surgeries (i.e., the trend net of surgery type fixed effects). This figure illustrates there is substantial growth in the use of minimally invasive techniques for these surgeries over this period—from 67.1% to 73.2%.

Appendix Figure A6 plots the share of target surgeries that are minimally invasive by surgery type over time. Appendix Table A5 summarizes these trends along with information on surgery prevalence. There are a few patterns worth noting. First, minimally invasive techniques have diffused more rapidly over this period for some surgeries than others. Surgeries with the largest increases in the share minimally invasive over this period include: shoulder distal clavicle resection (32.5 p.p.), shoulder rotator cuff repair (31.4 p.p.), elbow loose/foreign body removal (28.0 p.p.), and wrist/forearm carpal tunnel release (22.2 p.p.). Second, there has been staggered development of minimally invasive surgical techniques for different surgery types over time, leading to large cross-sectional variation across surgery types in the share minimally invasive in any given year. For instance, some surgeries were among the earliest to develop minimally invasive versions of the surgery, and for these surgeries, minimally invasive techniques had reached near universal adoption by the beginning of our analysis period; these surgeries include knee meniscectomy, shoulder loose/foreign body removal, knee synovectomy, and shoulder SLAP (Superior Labrum Anterior to Posterior) lesion repair.

Figure 11 also displays the share of target surgeries that are minimally invasive by Hospital Referral Region (HRR), shading the quintiles of this distribution. This figure illustrates there is wide variation across regions in the diffusion of minimally invasive surgery—with the slowest adopting 20% of regions (i.e., the 20% of regions with the lowest minimally invasive share) having a mean share minimally invasive roughly 10.8 p.p. less than the fastest adopting 20% of regions. Contextualizing this relative to aggregate growth rates, this difference suggests the slowest adopting 20% of regions are more than a decade behind the fastest adopting 20% of regions.

4.2 Interpretation of Estimates and Discussion

We explore the consequences of the documented diffusion patterns for minimally invasive techniques, combining this descriptive evidence with our main estimates of the causal effect of minimally invasive surgery relative to open surgery. We investigate how diffusion trends have impacted overall outcomes and contributed to trends in outcomes. Moreover, we analyze how altering the pace of diffusion could impact outcomes through some back-of-the-envelope calculations.

Impact of Diffusion on Outcomes We begin by exploring how diffusion of minimally invasive surgery over time has impacted outcomes. Specifically, we assess the aggregate implications of diffusion over time for outcomes through combining our descriptive evidence on the diffusion of minimally invasive surgery over time with the estimates of the causal effect of minimally invasive surgery relative to open surgery. Appendix Table A6 summarizes this analysis. Columns (1) and (2) report the estimated impact of the aggregate diffusion over time on the indicated outcome, in

levels and as a percent of the baseline mean. To further interpret the estimates, we compare these to the overall change in outcomes over this period (reported in column (3)) and calculate the share of the observed change in outcomes due to diffusion (reported in column (4)).

Among injured workers, the observed diffusion of minimally invasive surgery from 2008 to 2020 is responsible for meaningful improvements in outcomes over this period: a 1.9% decline in health care spending, 5.3% decline in opioid days supplied, 3.1% decline in revision surgeries, 1.8% decline in days out of work collecting temporary income benefits, 1.9% decline in permanent disability severity, and 1.7% decline in total workers' compensation insurance costs. We note that these patterns represent substantial declines in the overall expenses associated with the treatment of and recovery from workplace injuries, with diffusion over this period leading to an average decline of \$324 in post-surgical health spending, \$245 in post-surgical cash disability benefits, and \$569 in total post-surgical workers' compensation costs. Further, the improvement in outcomes due to the diffusion of minimally invasive surgery substantially impacts overall trends in these outcomes among these injured workers. For instance, based on our estimates, the diffusion of minimally invasive surgery can explain 15.0% of the reduction in health spending over this period. Moreover, the growth in cash disability benefits would have been 11.6% larger in the absence of the diffusion of minimally invasive surgeries seen over this period.

Potential Impact of Changing Diffusion Rate Next, we conduct some back-of-the-envelope calculations exploring the potential impact of policies aimed at speeding the diffusion of minimally invasive surgery. We note that these back-of-the-envelope calculations rely on several simplifying assumptions, so one should exercise appropriate caution in interpreting the results. For these calculations, we extrapolate from the estimates of the causal impact of minimally invasive surgery assuming constant treatment effects, and we consider impacts on outcomes over the analysis period (from 2008 to 2020) under the indicated scenario. These calculations focus on characterizing how increased diffusion impacts the outcomes analyzed. Given the positive impacts of minimally invasive surgery we document, this analysis informs us about the potential gains from speeding diffusion, without considering the feasibility of specific policies that may achieve faster diffusion (e.g., subsidies, payment policy, educational outreach) or the cost of implementing such policies. Through characterizing the potential benefits of promoting faster diffusion, this analysis informs policy discussions on whether efforts to promote faster diffusion may be worth considering and suggests further research is needed to estimate the costs and feasibility of specific policies.

First, we consider the impact of the overall diffusion rate. Evidence in Appendix Figure A6 suggests the share minimally invasive increases roughly linearly for surgery types with non-trivial growth over the analysis period. Motivated by this evidence, we approximate the impact of small changes in the diffusion rate by linearly scaling our estimates, and Appendix Table A6 column (5) displays these results. By the end of the analysis period, 20% faster diffusion of minimally invasive techniques among surgeries performed on injured workers would have decreased mean subsequent injury-related health care spending by \$389, mean days off work due to disability

by 2.7, mean severity of permanent disability by 7.8 p.p., and mean total subsequent workers' compensation costs by \$683.

Second, we explore the impact of reducing regional variation in diffusion patterns. Specifically, we consider the impact accelerating diffusion in slower-adopting regions to resemble diffusion in faster-adopting regions such that the share minimally invasive is equalized across regions at the maximum observed level across regions over this period. Appendix Figure A7 presents this analysis, where regions are colored according to the associated quintile of improvement in outcomes relative to the baseline observed diffusion patterns. Among injured workers, this acceleration in the rate of diffusion improves average outcomes (i.e., reduces subsequent health care spending and disability) by 6.2%. This improvement in outcomes varies widely by region, where the most affected one fifth of regions experience gains between 9.2% and 15.5% in mean outcomes, while the least affected one fifth of regions experience gains of at most 3.1% in mean outcomes.

5 Conclusion

This paper provides novel evidence on the impact of a major medical innovation—the move from traditional open surgery to minimally invasive surgery. Leveraging administrative data on injured workers in Texas and plausibly exogenous variation in surgical technique for orthopedic surgery, we estimate the causal impact of minimally invasive surgery relative to open surgery on subsequent health and disability outcomes. Our findings suggest that receiving minimally invasive surgery rather than open surgery substantially improves health, reduces subsequent health care spending, speeds return to work, reduces disability severity, and lowers associated social insurance costs. For example, our estimates suggest minimally invasive surgery (relative to open surgery) reduces subsequent injury-related health care spending by roughly a third—both because of a reduction in the complexity of the surgery and a large reduction in health care use over the two years following surgery. Estimates by service type indicate that minimally invasive surgery leads to a reduction in subsequent office visits, opioid use, and the likelihood of revision surgery. Leveraging detailed data on disability, our analysis illustrates minimally invasive surgery hastens return to work (by 37 days), reduces permanent disability severity (by 30%), and lowers associated social insurance costs (by 28%). These effects are large and suggest that the diffusion of these techniques in recent years is responsible for notable improvements in overall outcomes among injured workers.

In recent decades, the practice of medicine has evolved substantially, yet we still know very little about the impacts of medical innovations beyond pharmaceuticals. This represents a critical gap in existing research. Unlike new pharmaceuticals, medical innovations typically do not have to undergo clinical trials or prove their effectiveness. This lack of a formal review process—along with challenges isolating appropriate data and plausibly exogenous variation—means there is very little evidence on the causal impacts of these innovations. Understanding the effects of medical innovations is crucial because policy decisions can influence how they diffuse. The adoption of these innovations is often much slower than the adoption of new pharmaceuticals, given the spread

of these innovations often involves providers acquiring new skills or investing in complementary technology. And public policy has the potential to play a central role in influencing the diffusion of these innovations, as policymakers can create incentives to encourage faster adoption of new methods across regions and healthcare providers—for example, through the design of targeted subsidies, payment policy, and continuing education for providers.

Our findings show that a major medical innovation substantially improves subsequent health and disability. Through quantifying the impacts of minimally invasive surgery, our study sheds light on the potential benefits of policies that accelerate the adoption of this surgical innovation. Our study also highlights the need for more research quantifying the efficacy of specific policy proposals aimed at encouraging the diffusion of medical innovations (e.g., subsidies, payment policy, educational outreach) and points to the potential benefits of such policies. Our findings speak directly to the impacts of minimally invasive surgeries for musculoskeletal injuries, which are among the most common surgeries performed on prime-age adults. The large estimated impacts on health, health care use, and disability this context highlight the need for further research on the impacts of other types of minimally invasive surgeries and other medical innovations more broadly.

Our study also provides some broader insights on the impact of medical innovation on health and disability—and on the social insurance programs that cover these risks. Our study illustrates minimally invasive surgical methods (relative to conventional open surgical methods) dramatically improve health and disability outcomes—while at the same time substantially reducing downstream health care spending and social insurance costs. While innovation is often blamed for rising costs, our findings show the opposite is true for the key surgical innovation we analyze. In this way, our findings suggest that encouraging the adoption of effective medical innovations may be key to improving health, reducing disability severity, and lowering social insurance costs for individuals with work-limiting injuries. In addition, our findings suggest cost-effectiveness analyses of medical innovations should account for broader impacts on health and social insurance costs.

Figure 1: Distribution of Surgeon Intensity Instrument

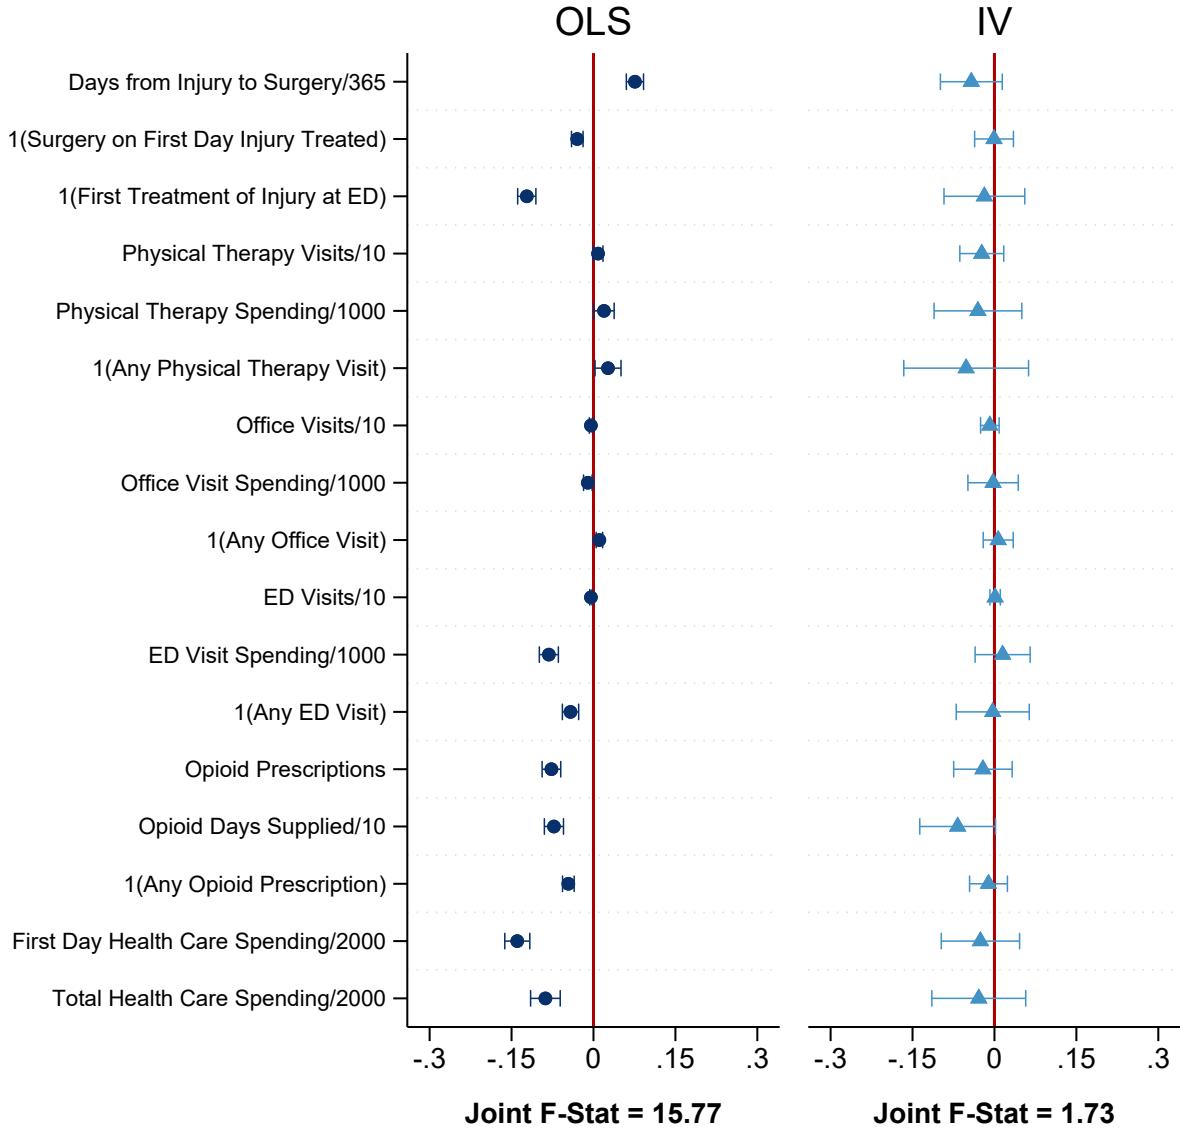

NOTES: This histogram displays the distribution of the UJIVE measure of surgeon intensity for minimally invasive surgery, $z_{id(i)}$, estimated from Equations (3) and (4) ($N = 93,350$ surgeries). See Section 2 for details on the estimation procedure.

Figure 2: Graphical Evidence on Validity of Surgeon Intensity Instrument

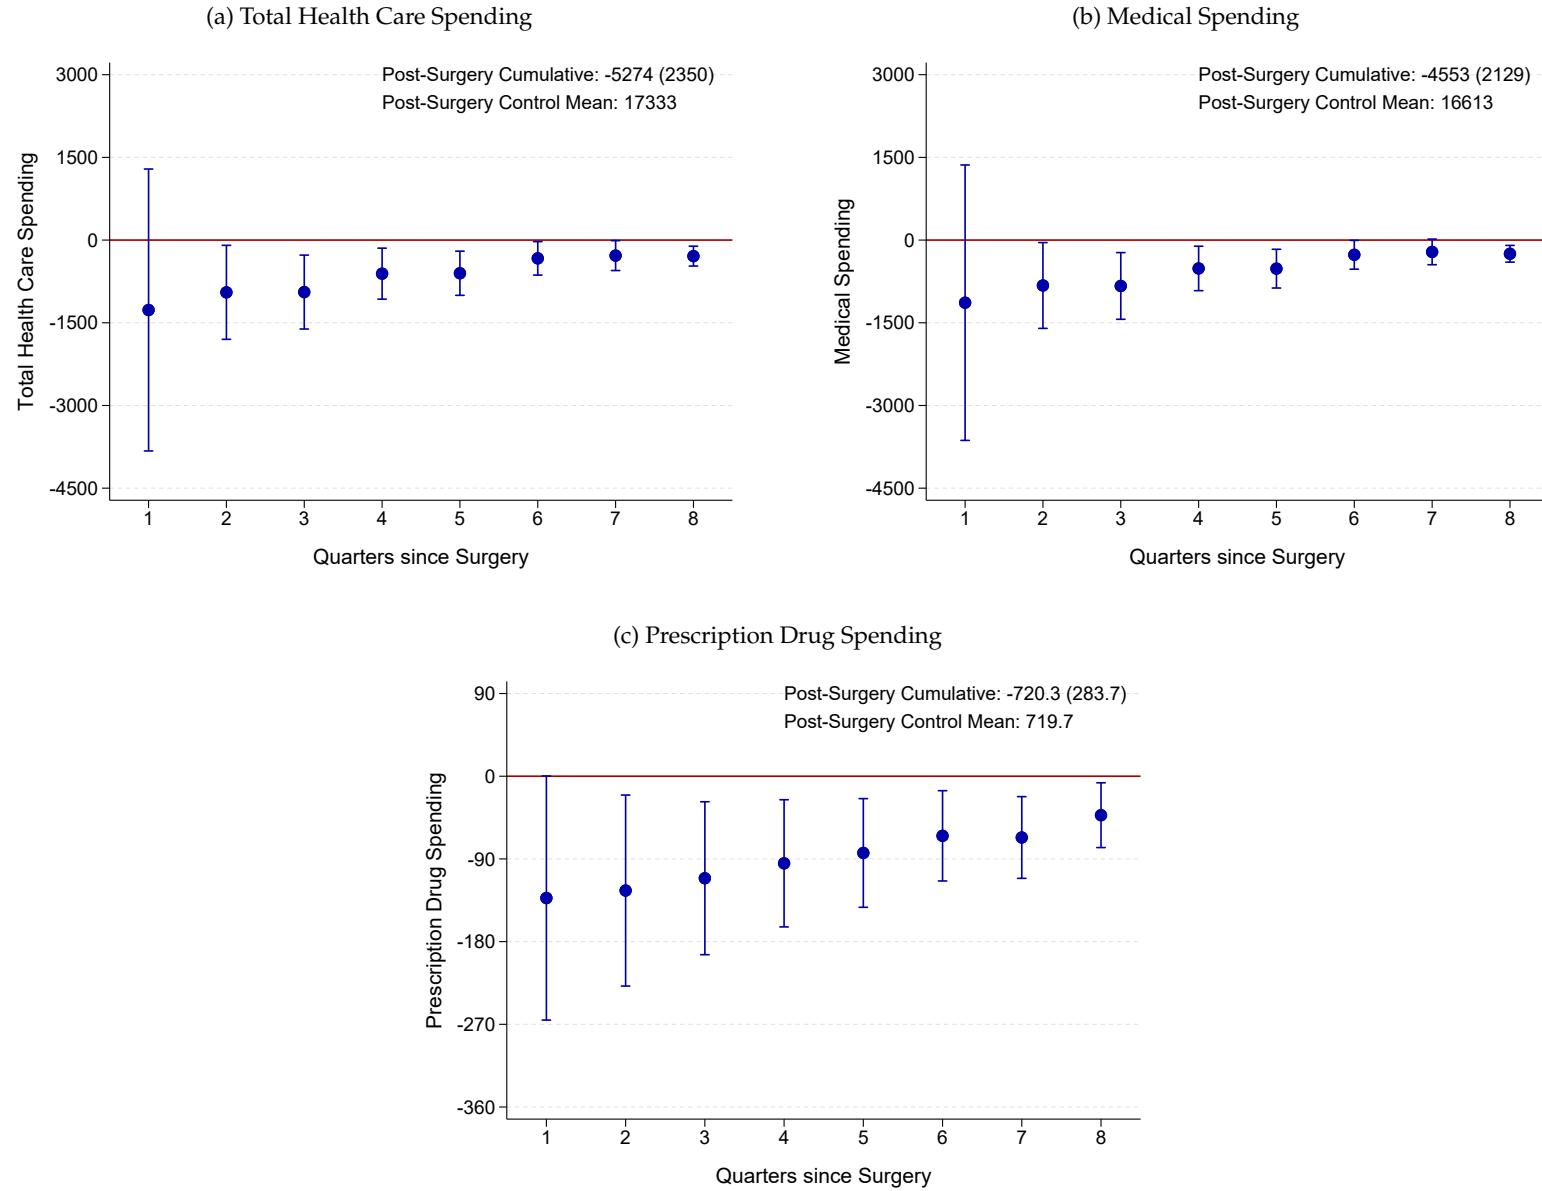

NOTES: This figure provides a graphical illustration of the validity of our instrument—relevance in panel (a) and independence in panel (b). Panel (a) plots the *actual* share of minimally invasive surgeries, residualized with respect to the baseline IV controls (i.e., age, sex, Hospital Referral Region, and surgery type by year), against 25 equal-sized bins of the surgeon intensity instrument. Panel (b) plots the *predicted* share of minimally invasive surgeries, residualized with respect to the same baseline controls, against the same bins. We construct each patient's predicted probability of minimally invasive surgery by regressing an indicator for minimally invasive surgery on all pre-surgery characteristics used in the balance test (shown in Figure 3). The coefficients reported at the top of each panel are estimated from Equation (2) using the underlying patient-level data, whereas the lines of best fit are obtained using the 25 plotted points.

Figure 3: Balance

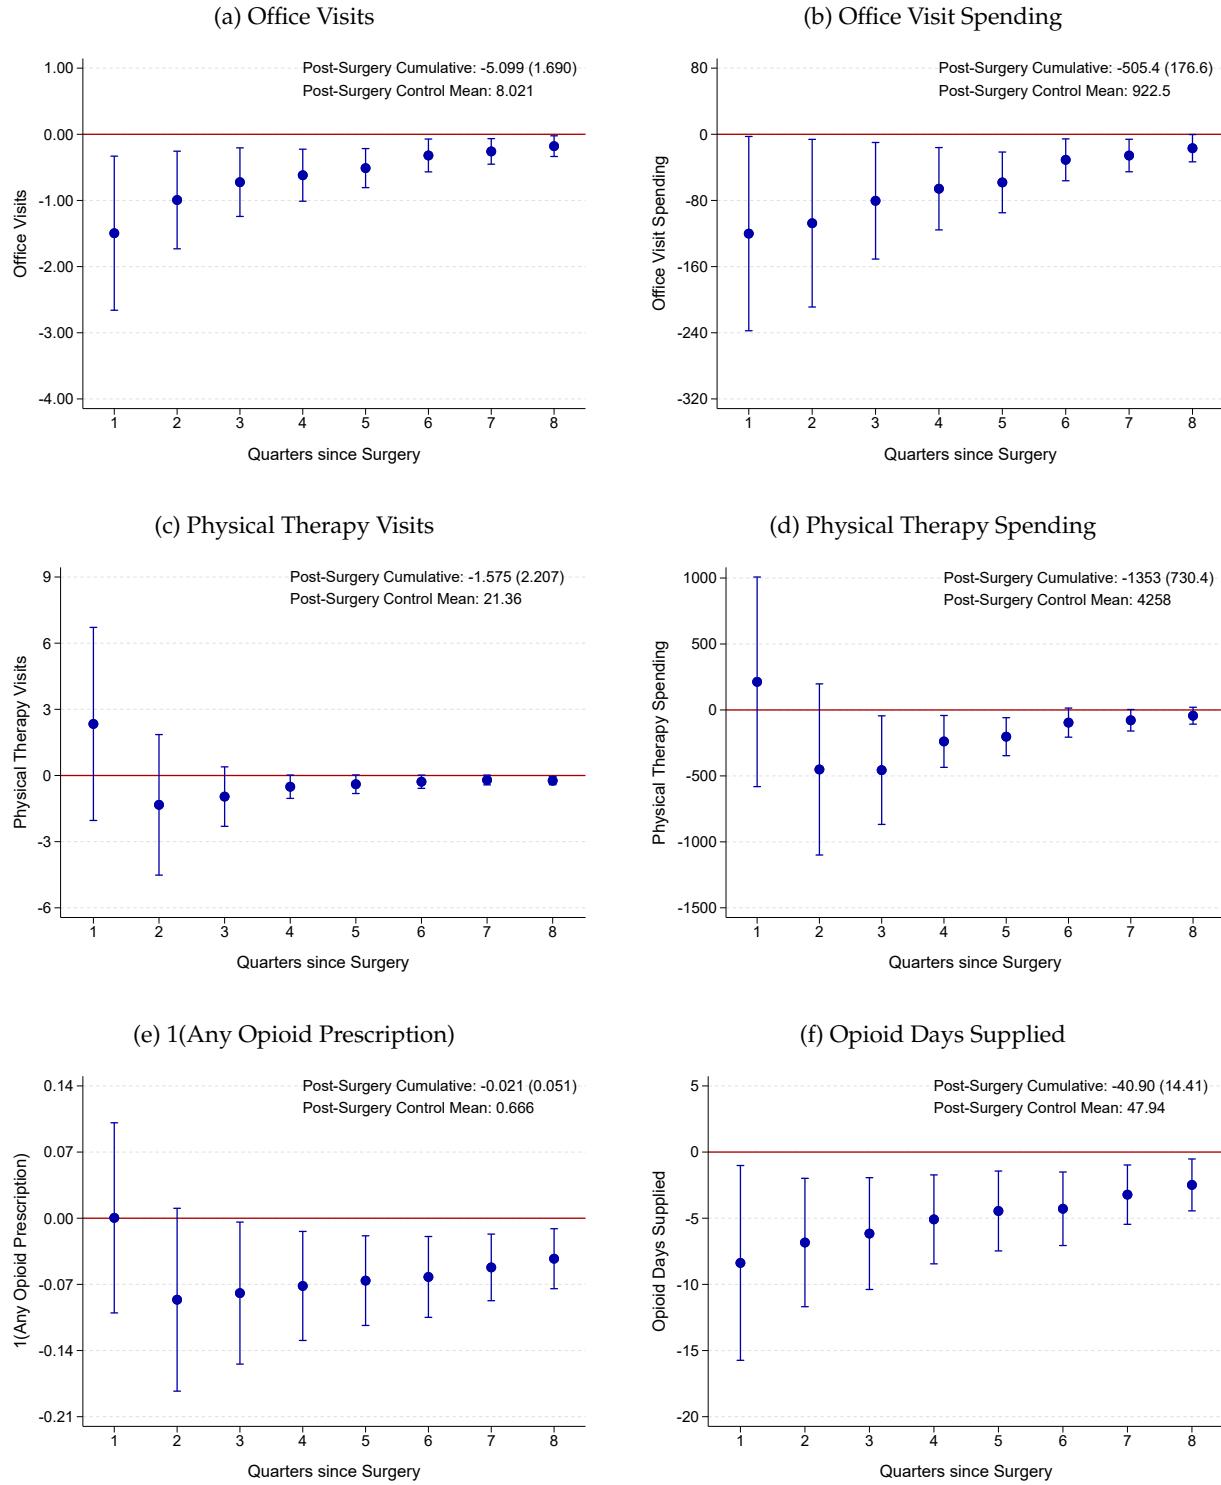

NOTES: This figure displays coefficients and 95% confidence intervals from regressions of pre-surgery characteristics on either the endogenous variable ($\text{Minimally-Invasive}_i$) or the surgeon intensity instrument ($z_{id(i)}$). The left panel—labeled OLS—shows estimated coefficients from separate bivariate regressions of each characteristic on the indicator for minimally invasive surgery. The right panel—labeled IV—shows estimated coefficients from separate regressions of each characteristic on the instrument, additionally controlling for the baseline IV controls (i.e., age, sex, Hospital Referral Region, and surgery type by year). The bottom of the figure reports the F-statistic from an F-test of joint significance in reverse multivariate regressions of the minimally invasive indicator on all pre-surgery characteristics (OLS panel) and of the instrument on all pre-surgery characteristics and the baseline IV controls (IV panel). Standard errors are clustered at the surgeon level. The estimated coefficients, standard errors, and p-values are reported in Appendix Table A1. See Appendix Section B.3 for more detail on the measures used for this analysis.

Figure 4: Dynamic Effects of Minimally Invasive Surgery on Health Care Spending

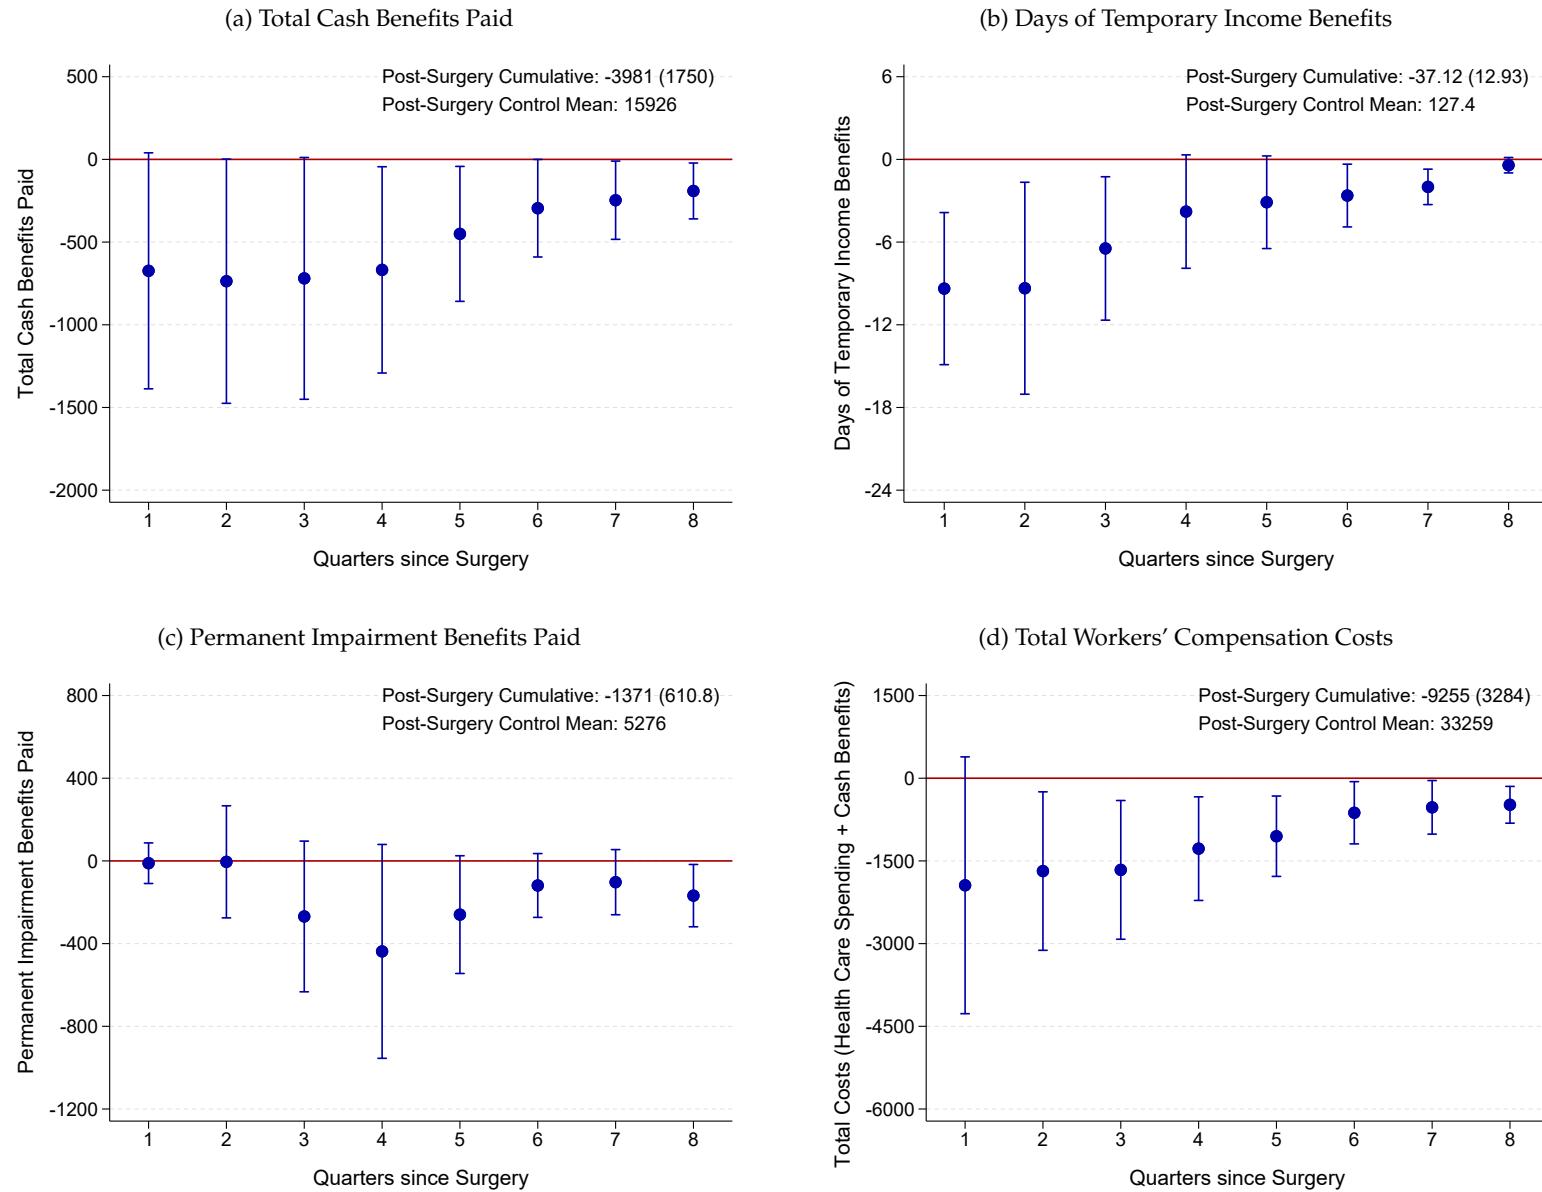

NOTES: This figure plots the estimated coefficients on the indicator for minimally invasive surgery from the IV specification outlined in Equations (1) and (2), along with 95% confidence intervals based on standard errors clustered at the surgeon level. Each quarter represents a separate regression, with the dependent variable measured over that quarter. The reported post-surgery cumulative effects are estimated using the dependent variables measured over all eight quarters. Post-surgery control means are calculated among patients who received open surgery.

Figure 5: Dynamic Effects of Minimally Invasive Surgery on Health Care Services

NOTES: This figure plots the estimated coefficients on the indicator for minimally invasive surgery from the IV specification outlined in Equations (1) and (2), along with 95% confidence intervals based on standard errors clustered at the surgeon level. Each quarter represents a separate regression, with the dependent variable measured over that quarter. The reported post-surgery cumulative effects are estimated using the dependent variables measured over all eight quarters. Post-surgery control means are calculated among patients who received open surgery.

Figure 6: Dynamic Effects of Minimally Invasive Surgery on Disability and Social Insurance Costs

NOTES: This figure plots the estimated coefficients on the indicator for minimally invasive surgery from the IV specification outlined in Equations (1) and (2), along with 95% confidence intervals based on standard errors clustered at the surgeon level. Each quarter represents a separate regression, with the dependent variable measured over that quarter. The reported post-surgery cumulative effects are estimated using the dependent variables measured over all eight quarters. Post-surgery control means are calculated among patients who received open surgery.

Figure 7: Heterogeneity by Pre-Surgery Patient Characteristics

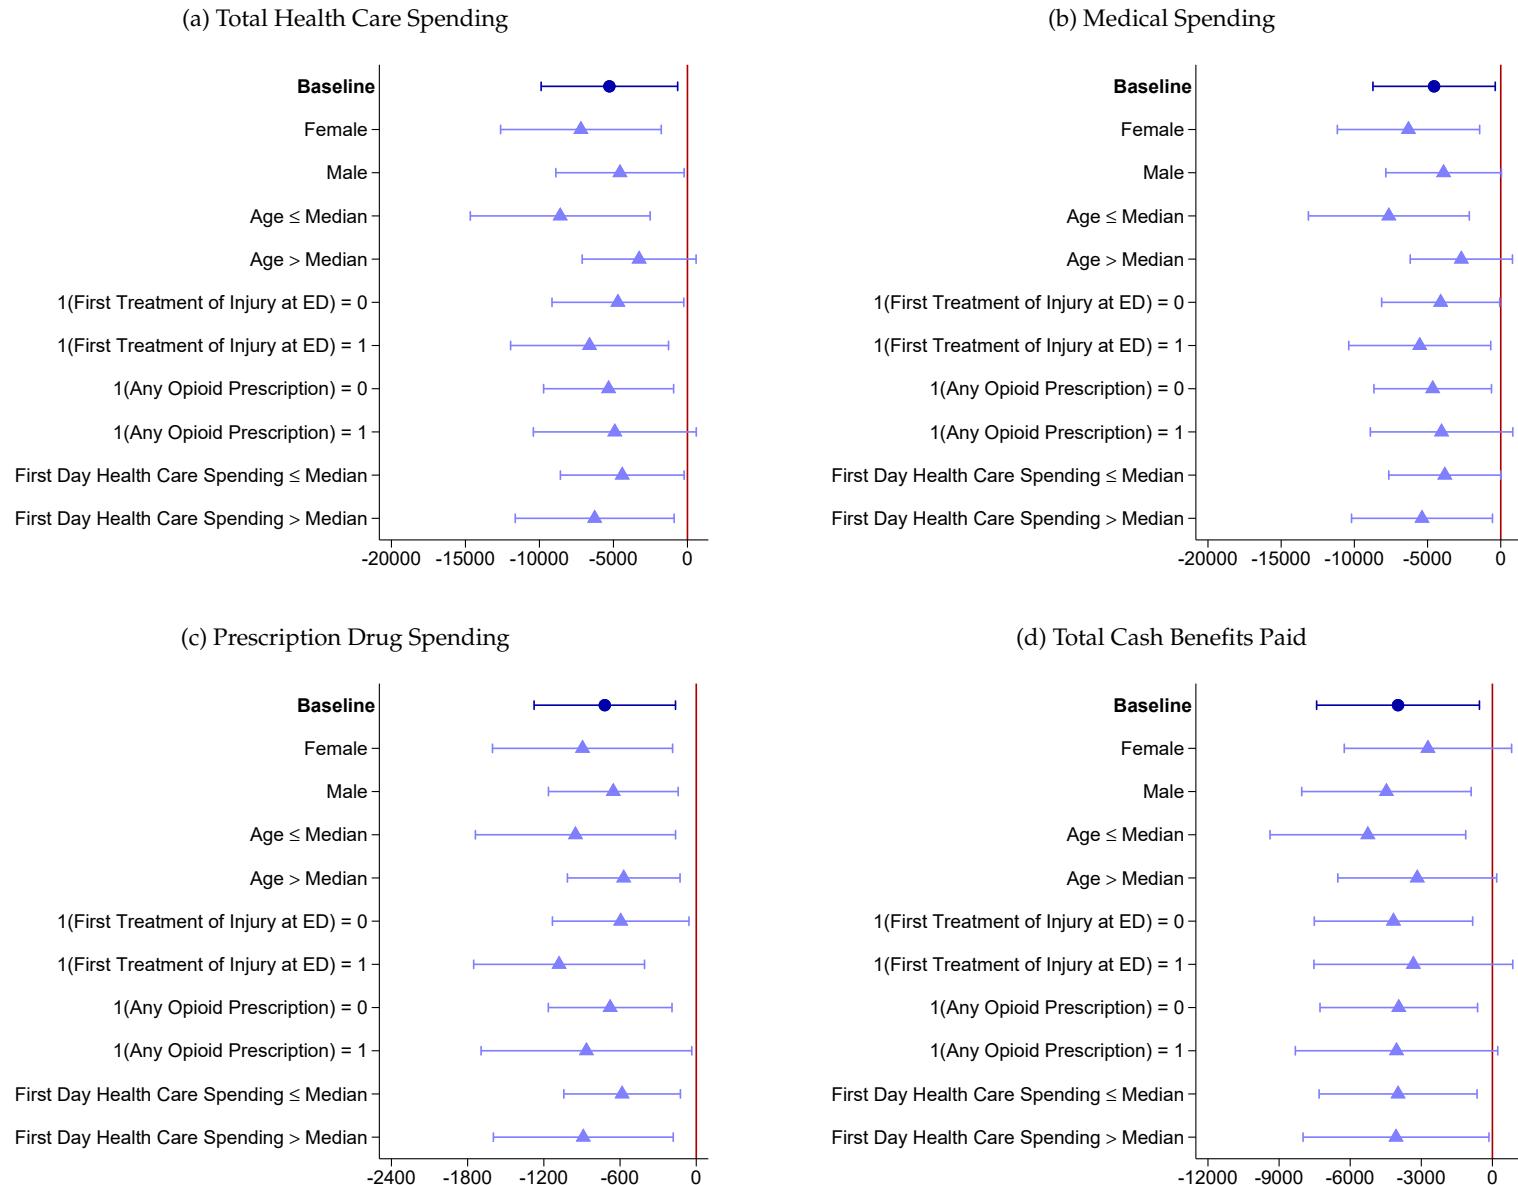

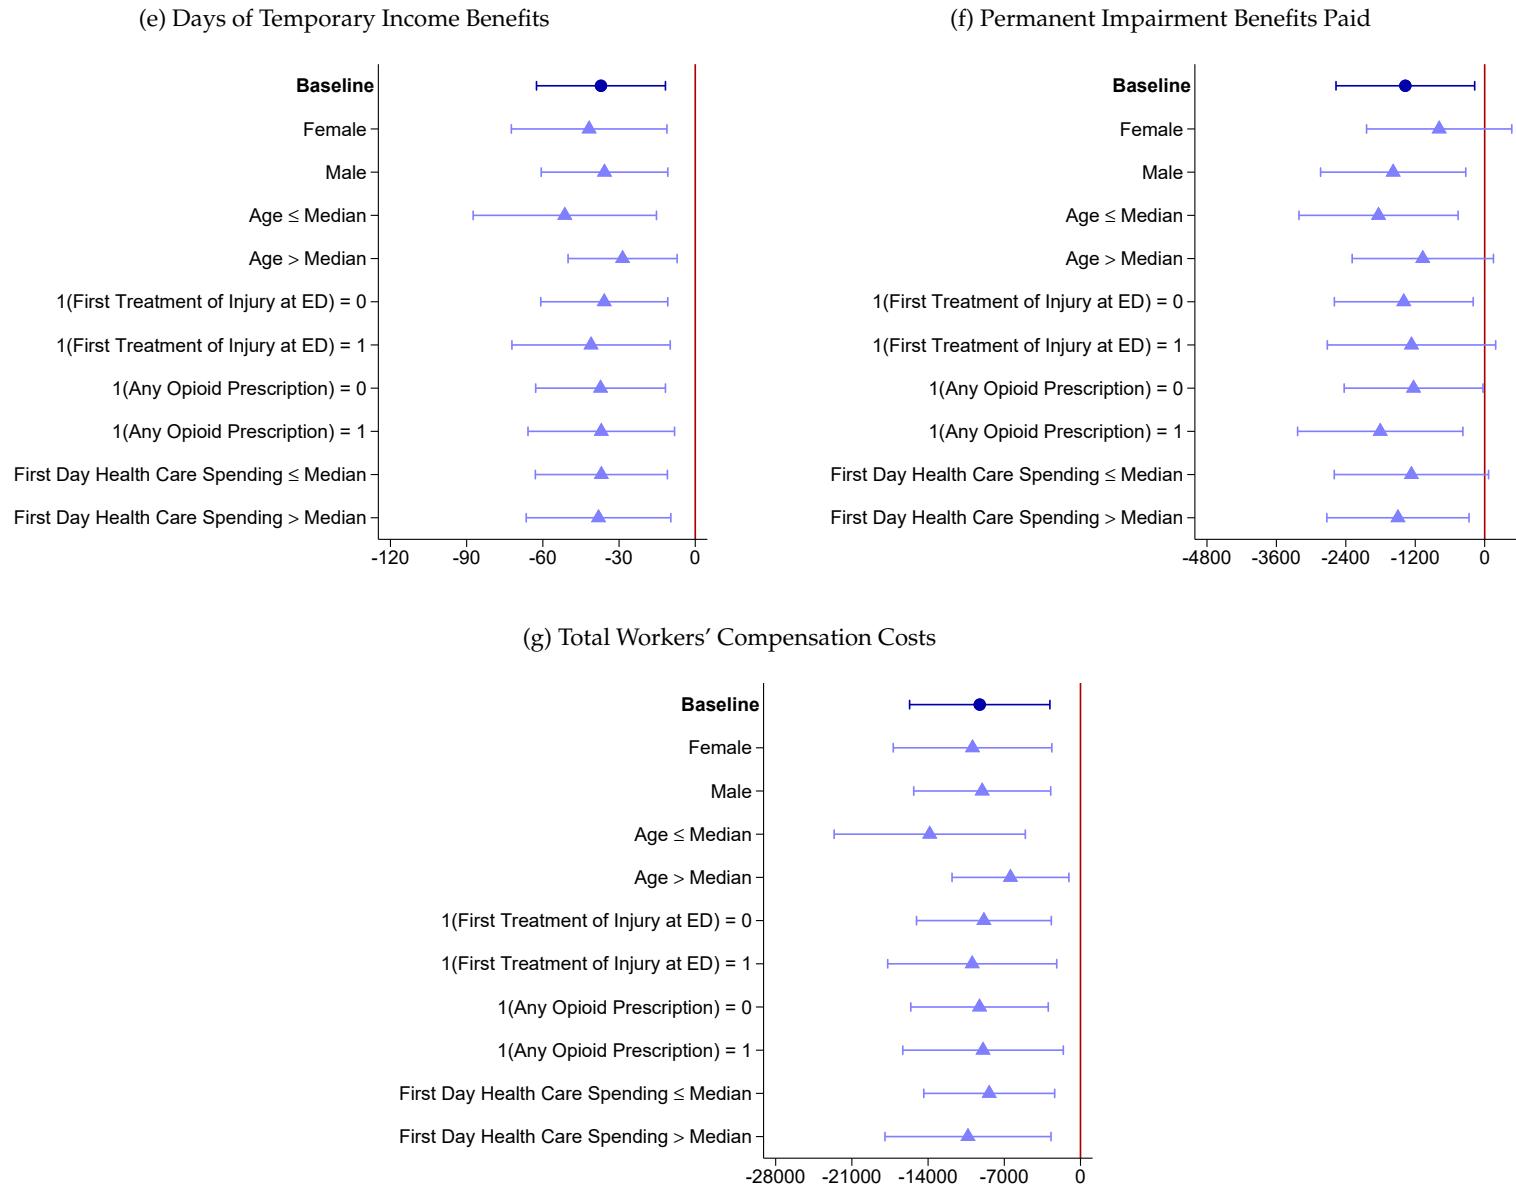

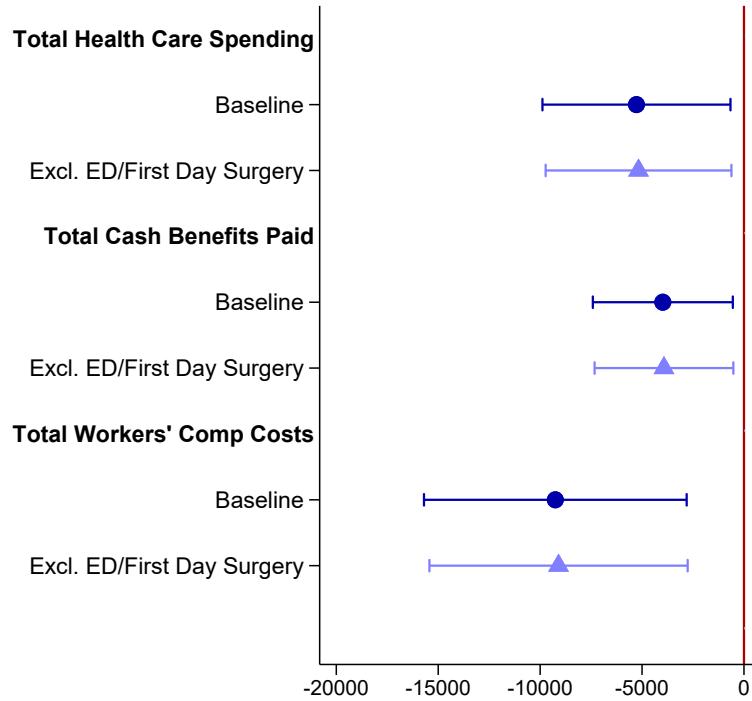

Figure 7 (Continued)

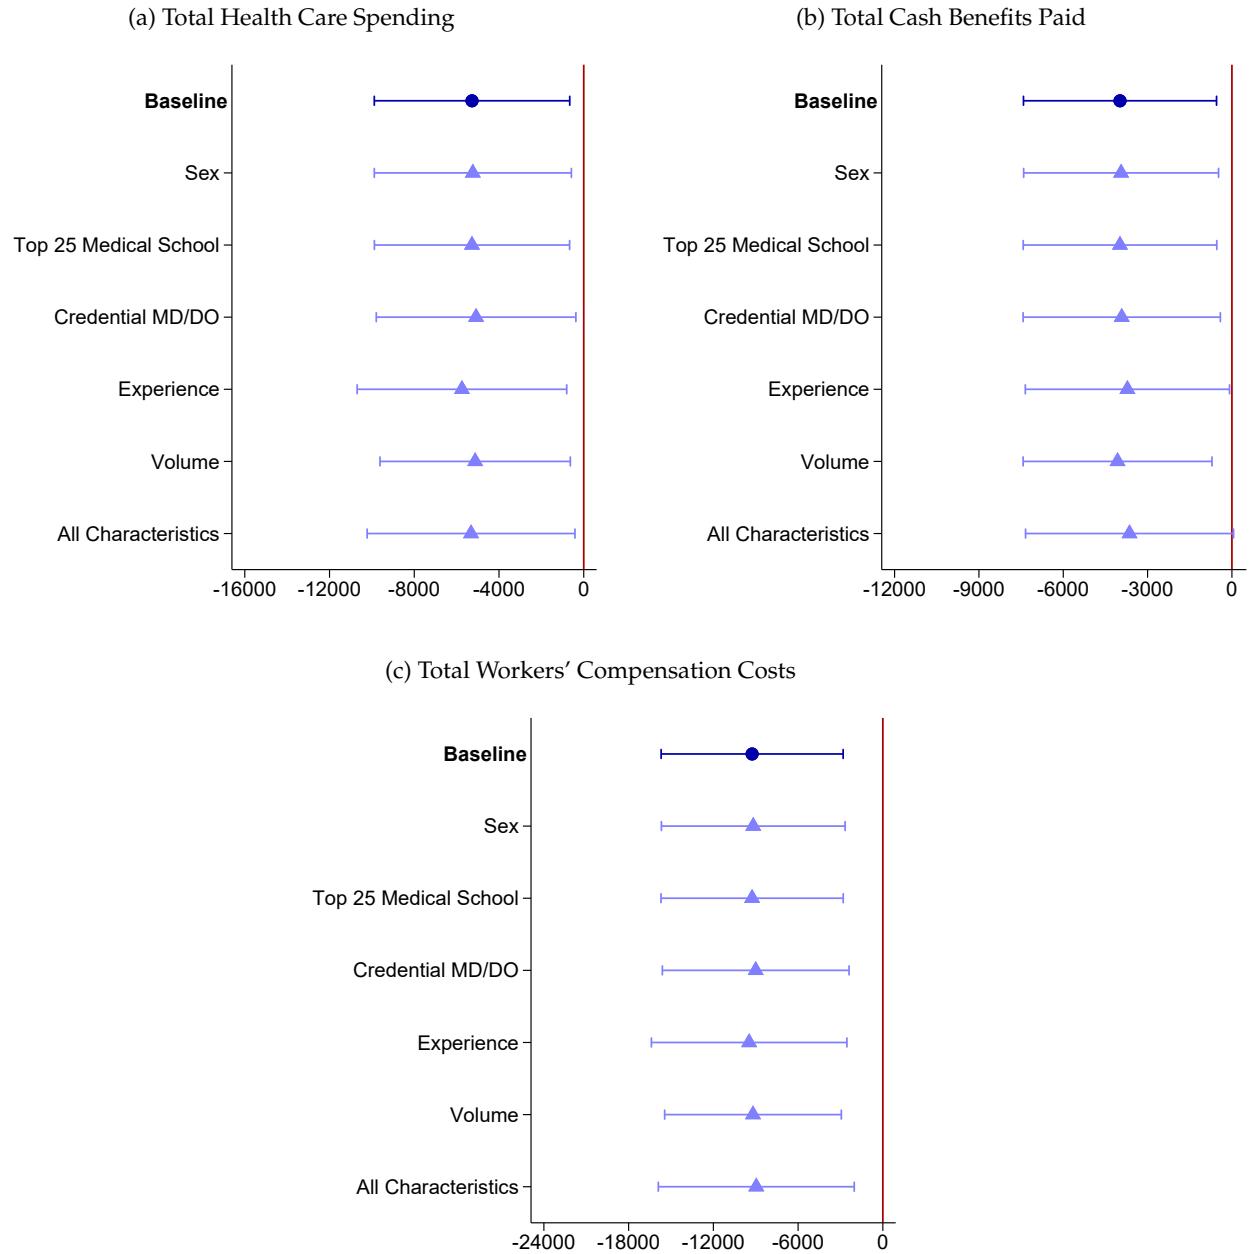

NOTES: This figure plots the estimated coefficients on the indicator for minimally invasive surgery from the IV specification outlined in Equations (1) and (2), estimated separately for each subgroup denoted on the vertical axis, along with 95% confidence intervals based on standard errors clustered at the surgeon level. The dependent variables are measured over the two years following surgery. The baseline estimates are reproduced at the top of each panel. Appendix Tables A3 and A4 report the estimated coefficients, standard errors, and p-values for each subgroup and for the differences between subgroups within each category (e.g., female vs. male patients), respectively.

Figure 8: Robustness—Excluding Emergency Surgeries

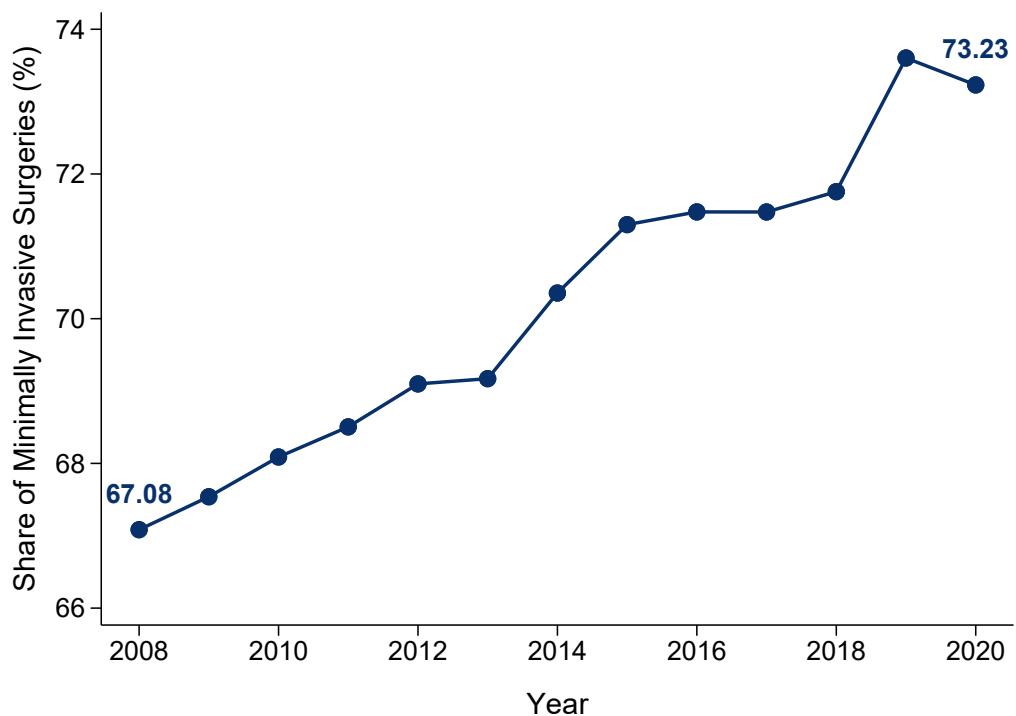

NOTES: This figure plots the estimated coefficients on the indicator for minimally invasive surgery from the IV specification outlined in Equations (1) and (2), along with 95% confidence intervals based on standard errors clustered at the surgeon level. The dependent variables are measured over the two years following surgery. For each of the three dependent variables highlighted in bold on the vertical axis, we first reproduce the baseline estimates and then re-estimate the IV specification excluding approximately 2.5% of patients (2,346 out of 93,350) who could have had surgery on an emergency basis—specifically, those who had surgery (i) on the same date as an ED visit or (ii) on the first day their injury was treated.

Figure 9: Robustness—Controlling for Other Surgeon Characteristics

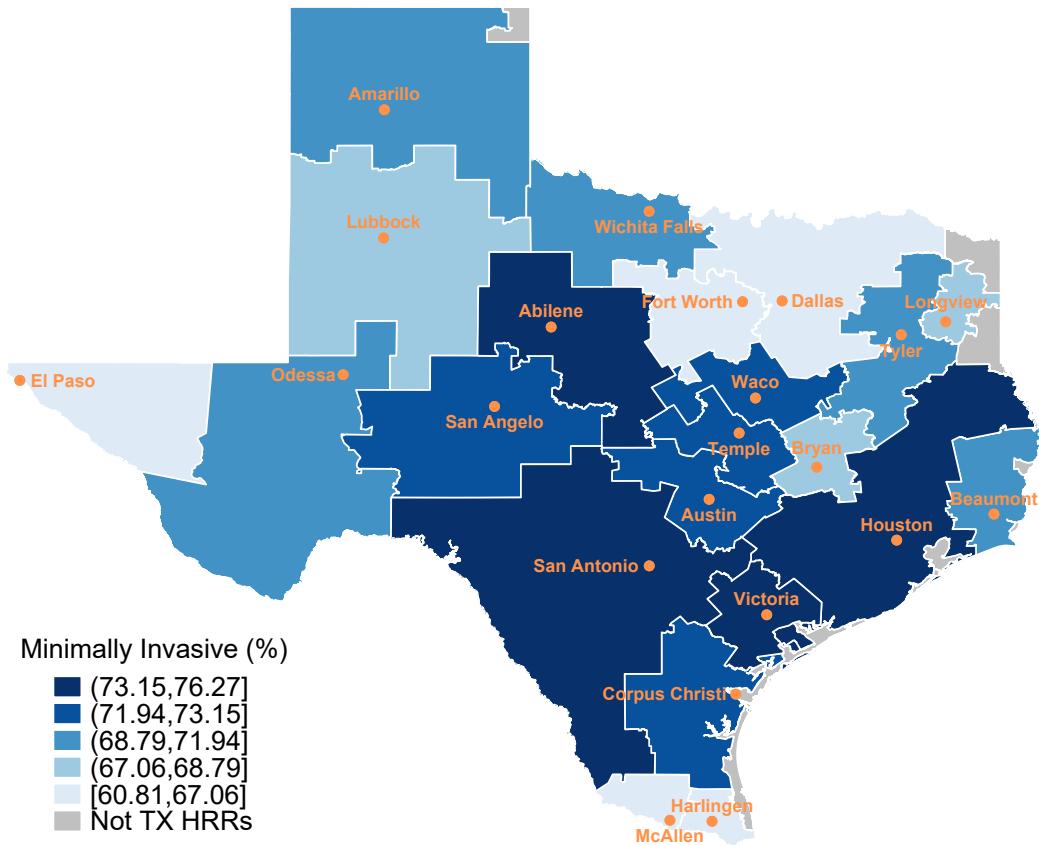

NOTES: This figure plots the estimated coefficients on the indicator for minimally invasive surgery from alternative specifications that add surgeon characteristics to the baseline IV specification outlined in Equations (1) and (2), along with 95% confidence intervals based on standard errors clustered at the surgeon level. The dependent variables are measured over the two years following surgery. For each panel, we first reproduce the baseline estimates (top row) and then re-estimate the IV specification adding the indicated surgeon characteristics individually (second through sixth rows) and jointly (bottom row).

Figure 10: Trends in Share of Minimally Invasive Surgeries

NOTES: This figure displays trends in the share of minimally invasive surgeries within our analysis sample, excluding years with partial coverage (i.e., 2007 and 2021). To account for changes in surgery composition, we compute the share using a mean-preserved residualized indicator, obtained by first residualizing the indicator for minimally invasive surgery with respect to surgery type and then adding back the overall mean to preserve the original level.

Figure 11: Share of Minimally Invasive Surgeries Across Hospital Referral Regions in Texas

NOTES: This figure displays the geographic distribution of minimally invasive surgery shares, grouped into quintiles across 22 Texas Hospital Referral Regions (HRRs) within our analysis sample. We exclude approximately 1.2% of patients (1,137 out of 93,350) who lived in non-Texas HRRs at the time of surgery. To highlight geographic variation, we compute the share using a mean-preserved residualized indicator, obtained by first residualizing the indicator for minimally invasive surgery with respect to age, sex, surgery type, and surgery year, and then adding back the overall mean to preserve the original level.

Table 1: Top 25 Target Surgeries by Volume

	Number (1)	Share (2)	Mean Characteristics		
			Minimally Invasive (3)	Patient Male (4)	Patient Age (5)
Knee meniscectomy	26,884	0.288	0.999	0.696	48.08
Shoulder rotator cuff repair	17,646	0.189	0.631	0.716	53.33
Knee ACL/PCL reconstruction	6,623	0.071	0.924	0.711	36.77
Shoulder subacromial decompression	5,093	0.055	0.921	0.673	47.65
Wrist/forearm fracture fixation	4,520	0.048	0.082	0.491	50.48
Shoulder biceps tenodesis	3,658	0.039	0.237	0.810	50.79
Wrist/forearm carpal tunnel release	2,774	0.030	0.340	0.437	46.89
Spine discectomy	2,198	0.024	0.000	0.829	41.84
Hand phalangeal shaft fracture fixation	2,174	0.023	0.376	0.834	39.74
Hand distal phalangeal fracture fixation	2,167	0.023	0.202	0.887	40.23
Shoulder loose/foreign body removal	2,091	0.022	0.998	0.710	46.57

NOTES: This table lists the 25 most common target surgeries in the analysis sample, ordered by volume (top to bottom). The first two columns report the absolute number and relative share of each surgery. The next three columns report the share of surgeries that are minimally invasive, the share of male patients, and the mean age of patients, respectively.

Table 2: Descriptive Statistics for Patients

NOTES: This table reports the estimated coefficients on the indicator for minimally invasive surgery from the IV specification outlined in Equations (1) and (2). Each row represents a separate regression, with the dependent variable measured on the surgery date in Panel A and over the two years following surgery in Panels B and C. Columns (1) and (2) report the mean and standard deviation of each dependent variable, calculated among patients who received open surgery. Columns (3)–(5) report the estimated coefficients, standard errors, and p-values, respectively. Column (6) reports the estimated effects in percentage terms relative to the control means.

The Impact of Medical Innovation on Health and Disability

ONLINE APPENDIX

A Dataset on Musculoskeletal Surgeries Performed Using Minimally Invasive or Open Techniques

For this study, we compile a novel dataset covering all musculoskeletal surgeries that can be performed using either minimally invasive or open surgical techniques. This dataset consists of *minimally invasive* Current Procedural Terminology (CPT) codes and their corresponding *open* CPT codes—procedures that achieve the same goal but require larger incisions—by using various sources and cross-validation processes. We begin by collecting all CPT codes for minimally invasive musculoskeletal surgeries (e.g., arthroscopy). We then classify these CPT codes based on the associated body part and specific procedure (e.g., anterior cruciate ligament (ACL) repair in the knee), which we refer to as a *surgery type*.

Next, for each surgery type, we identify the corresponding open CPT codes using various methods. Specifically, we first conduct an extensive review of the medical literature that directly provides CPT code information for minimally invasive procedures and their alternative open surgical options with clinical equivalence in musculoskeletal surgeries. When such explicit information is not available in the medical literature, we primarily use two websites—the American Academy of Professional Coders and Generative Healthcare AI—to identify candidate open CPT codes by retrieving all CPT codes associated with the same body part and a similar surgical purpose.²⁰ We then carefully examine the description of each candidate CPT code to determine whether it corresponds to an open CPT code that performs an identical or nearly identical surgical procedure to the minimally invasive CPT code of interest. Finally, we cross-validate our data, particularly classifications not directly derived from the medical literature, using additional sources such as medical billing and coding forums and coding guideline articles.

Using the approach described above, we obtain a total of 290 CPT codes—134 for minimally invasive codes and 156 for open codes—for musculoskeletal surgeries across 98 surgery types (defined by the indicated body part and specific procedure). Among these surgery types, we exclude certain ones if: (i) a comparable open option is unavailable, (ii) the minimally invasive CPT codes pertain to diagnosis, or (iii) an open CPT code covers multiple surgery types. After these exclusions, our final dataset includes 81 surgery types in which both minimally invasive and open options are available, with 114 minimally invasive codes and 146 open codes, each assigned to a single surgery type.

²⁰These two websites can be accessed at the following URLs: <https://www.aapc.com> and <https://genhealth.ai>.

B Data Construction

B.1 Sample Definition

We define an *encounter* as all interactions between a patient and healthcare provider(s) on a single date. As such, from a data perspective, each encounter typically generates multiple medical bills initiated that day. We use all medical bills submitted via the CMS-1500 form (for non-institutional providers) and the CMS-1450 form (for institutional providers) to construct the set of medical bills associated with each encounter. This allows us to more comprehensively identify surgery cases of interest—as either form can be used to bill for a day surgery—and to more accurately capture all medical services the patient receives. Finally, it is natural for a single patient to have multiple encounters, as they may receive medical services on different dates.

To construct our main sample of *target encounters*, we first consider all encounters in which an injured worker had any surgery listed in our musculoskeletal surgery dataset described in Appendix A. (We refer to such surgeries as *target surgeries*.) The sample is then limited to encounters where the target musculoskeletal surgical procedure has the highest billed amount among all procedures received on the encounter date, ensuring that it was the *primary* medical service that day. For individuals with multiple target musculoskeletal surgeries, we consider only the first surgery, as subsequent surgeries and health care are endogenous to it. We focus on surgeries performed between June 2007 and April 2021, as surgeons can be consistently identified using the National Provider Identifier (NPI), which became effective in May 2007, and we can measure various outcomes for two years following the surgery, given that our data end in July 2023.²¹ We exclude surgeries if we cannot reliably identify a rendering NPI (see Section B.2). Additionally, we drop surgeries performed by doctors whose share of surgeries in emergency or urgent care settings is 10% or greater, as the nature of these settings may influence their decisions regarding minimally invasive versus open surgery differently from other doctors. Surgeries with missing values for sex, age, and hospital referral region, as well as those performed more than two years after the claim start date, are also dropped.²² Finally, we require each category in the full set of fixed effects used for instrument construction—detailed in Section 2—to have at least 10 observations (i.e., every surgery group has at least 10 observations for each year). Our baseline sample consists of 93,350 surgeries performed by 978 doctors.

B.2 Identifying Rendering Surgeons

We first construct a dataset that includes only National Provider Identifiers (NPIs) for general surgeons and orthopedic surgeons, using the National Plan and Provider Enumeration System (NPPES) file (CMS, 2024). Specifically, we retain only NPIs that represent individuals (as opposed to organizations) with 25 provider taxonomy codes associated with a Medicare Specialty Code of

²¹We apply a three-month margin to account for potential data lags.

²²We define the first medical service date for the injury as the claim start date.

02 and define them as general surgeons. Among these general surgeons, we further classify those with eight provider taxonomy codes that have a prefix of 207X as orthopedic surgeons.²³

B.3 Pre-Surgery Claim Characteristics

As discussed in the main text, we use the pre-surgery claim characteristics for the balance analysis. One set of pre-surgery characteristics is proxies for the severity of the injury, which include an indicator for whether the claim originated with an emergency department visit, log of medical spending on the first day of claim, indicator for surgery on first day of claim. For these measures, we define variables based on the date the injured worker first received medical treatment for the injury.²⁴ Another set of characteristics includes the number of days between injury and surgery and measures of health care utilization before the surgery. The pre-surgery health care utilization measures include pre-surgery physical therapy visits, opioid use, and medical spending. Pre-surgery health care utilization measures summarize utilization during the first two weeks of the claim and exclude the three days before surgeries take place to ensure we are not capturing health care related to the surgery that occurs in the few days before the surgery. Thus, analysis with these measures focuses on the 87.2% of claims with at least 17 days between the claim start date and the surgery.

C Supplemental Analysis

Our main analysis focuses on patients who received the target surgeries. Given this, it is natural to ask: do patients select into receiving surgery based on doctor propensities to do minimally invasive versus open surgery? While selection of this type would only bias our estimates if this selection were related to patient level determinants of our outcomes of interest, we directly explore the possibility of selection into surgery based on doctor minimally invasive intensity. Section 2 in the main text summarizes this analysis, and below we provide further details.

For this analysis, we define a broader sample of individuals potentially eligible to have surgery: all patients in the data who ever had an office visit with an orthopedic surgeon who is represented in our baseline analysis. This analysis is premised on the fact that patients typically have an office visit with their surgeon prior to surgery, but not all office visits with surgeons result in later surgery. Among this broader sample of patients potentially eligible to have surgery, we first estimate the following regression:

$$Surgery_i = \mathbf{X}_i\zeta + \varphi_{k(i)t(i)} + \nu_i, \quad (\text{A1})$$

where i denotes patient, $k(i)$ denotes the diagnosis of the patient from an office visit with surgeon, and $t(i)$ denotes the year of the initial visit with the surgeon. $Surgery_i$ indicates that the patient has

²³For a complete list of Medicare specialty and provider taxonomy codes, see here: <https://data.cms.gov/provider-characteristics/medicare-provider-supplier-enrollment/medicare-provider-and-supplier-taxonomy-crosswalk>.

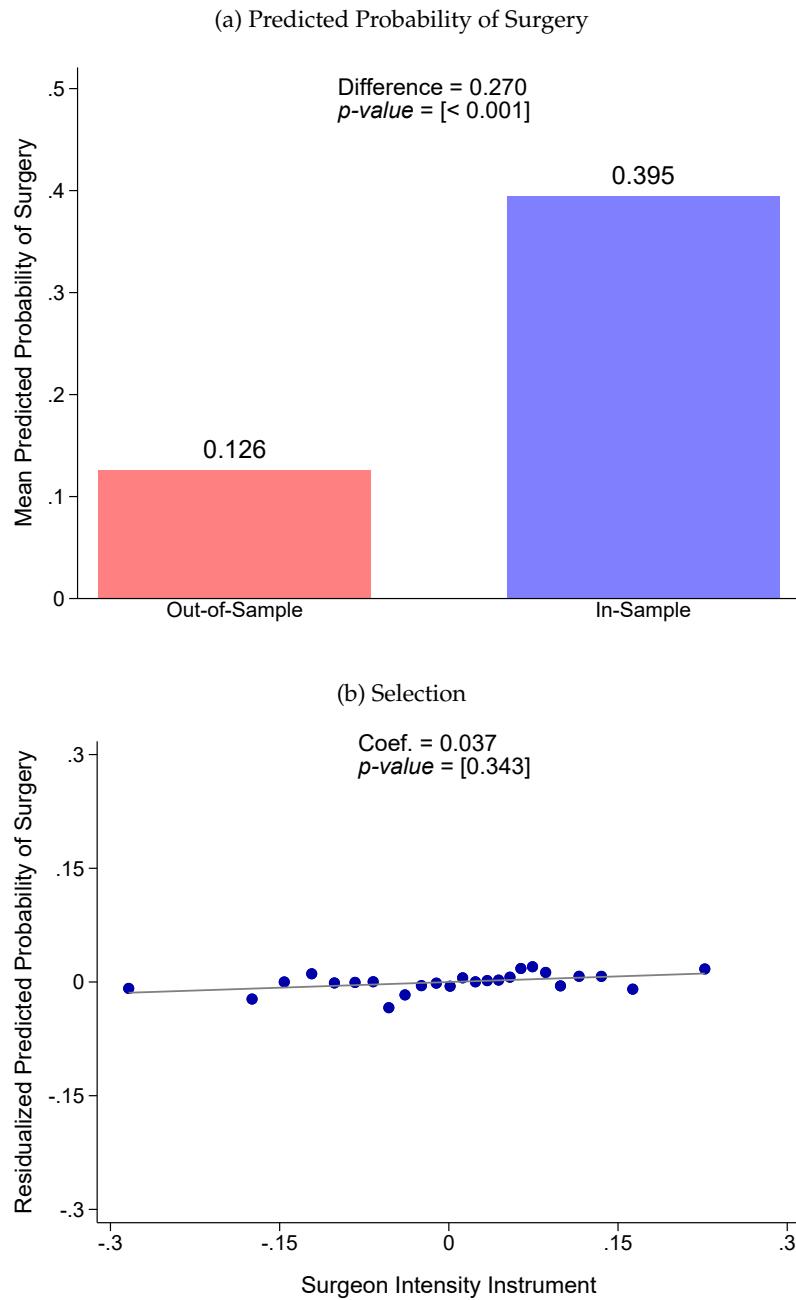

²⁴The workers' compensation administrative data record the year and month of the injury, not the exact date. Therefore, we define the claim start date using the date of the first medical treatment received for the injury.

surgery within three months of their initial office visit with the surgeon, $\varphi_{k(i)t(i)}$ represents diagnosis by year fixed effects, and X_i represents additional controls for demographics (individual age and sex) and medical market (Hospital Referral Region). When constructing $\varphi_{k(i)t(i)}$, we consider two ways to characterize diagnosis: (a) diagnosis from the initial office visit with the surgeon and (b) diagnosis at the most recent pre-surgery office visit with the surgeon within 3 months of the initial visit. As in the baseline IV estimation, we require each category of fixed effects to have at least ten observations.

After estimating Equation (A1) using the sample of patients potentially eligible to have surgery, we then use the coefficients from this model to predict the likelihood that patients undergo surgery. Appendix Figure A1 Panel (a) reports the means of this ex ante predicted probability of surgery by eventual surgery status and indicates this ex ante predicted probability is highly predictive of whether patients actually receive surgery. For patients who receive surgery, we estimate the average ex ante predicted probability of having surgery is 39.5%. For patients who do not receive surgery, we estimate the average ex ante predicted probability of having surgery is 12.6%.

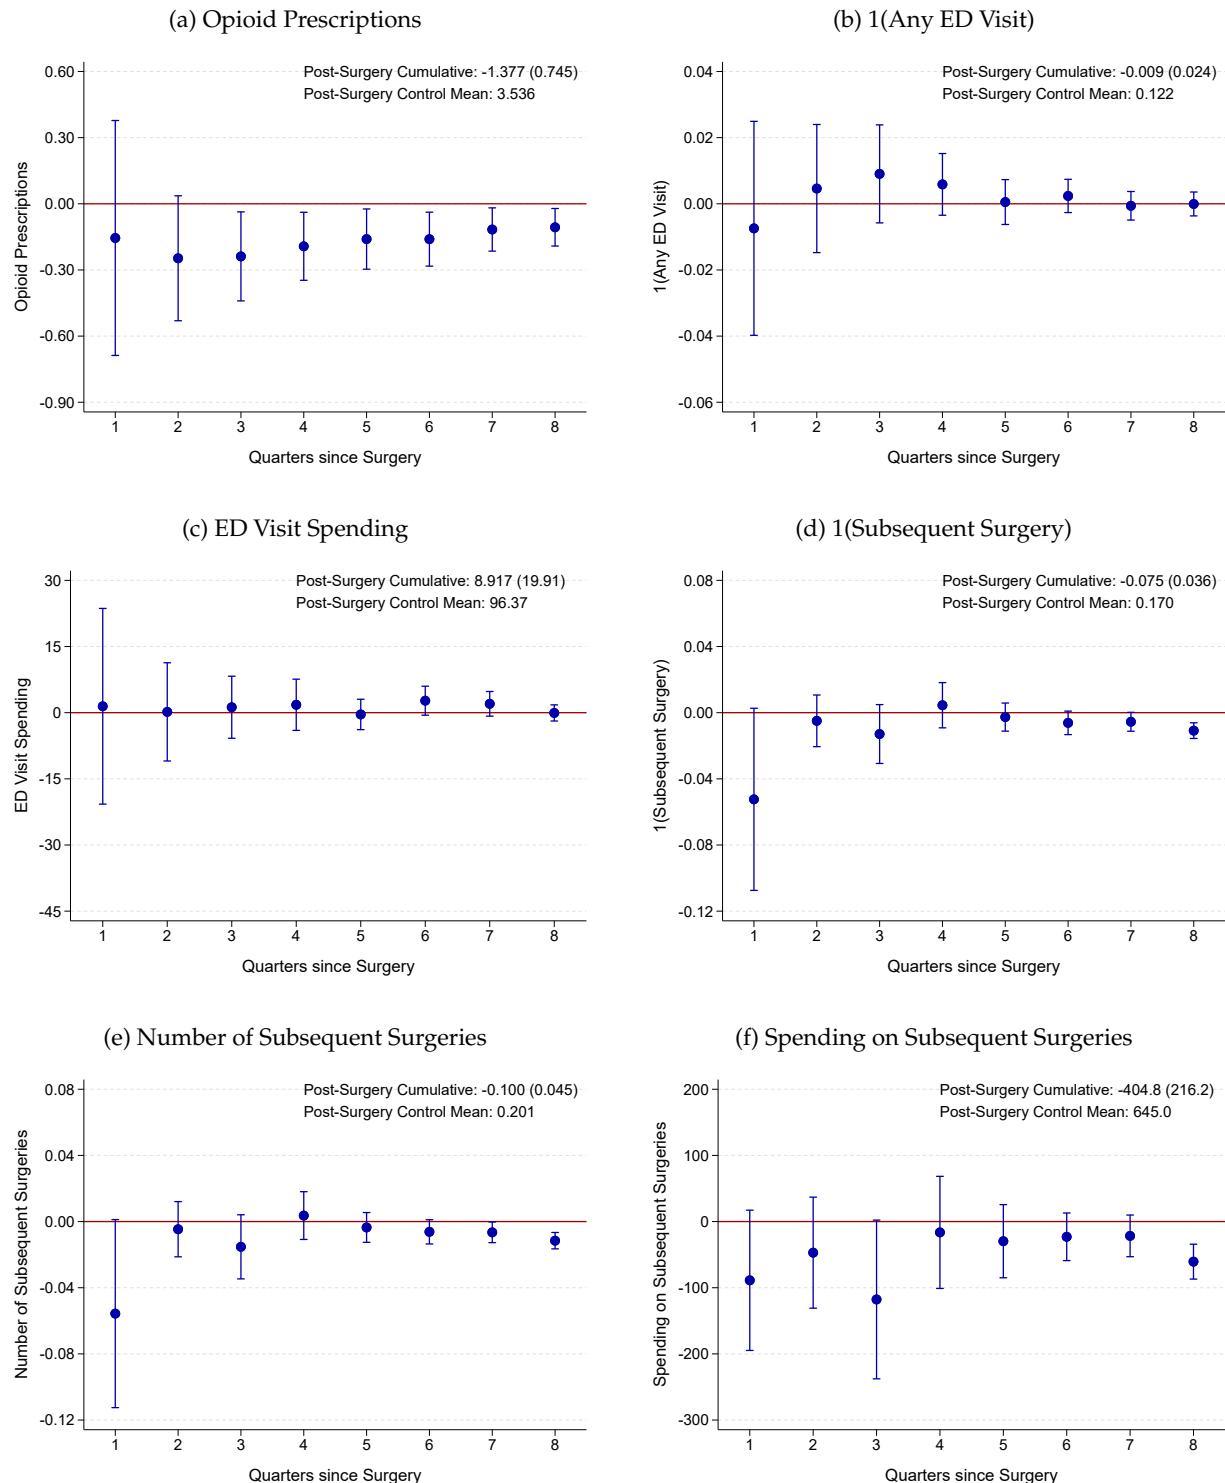

We then test for balance in this predicted surgery measure in our main analysis sample by setting it as the dependent variable in Equation (2) and regressing it on the instrument, $z_{id(i)}$, as we did with predetermined characteristics in Figure 3. Appendix Figure A1 Panel (b) reports the coefficient on $z_{id(i)}$ and an associated plot that relates the residualized predicted probability of surgery to $z_{id(i)}$. This analysis provides no evidence that the predicted likelihood of having a surgery based on baseline characteristics is associated with the surgeon's minimally invasive intensity measure. The coefficient on $z_{id(i)}$ is a statistically insignificant 0.037, and the residualized predicted probability of surgery is flat across the distribution of $z_{id(i)}$. This analysis suggests the predicted probability of surgery is not related to the instrument and thus the ex ante predicted probability of surgery is not related to our identifying variation.

Figure A1: Selection into Surgery by Surgeons' Minimally Invasive Intensity

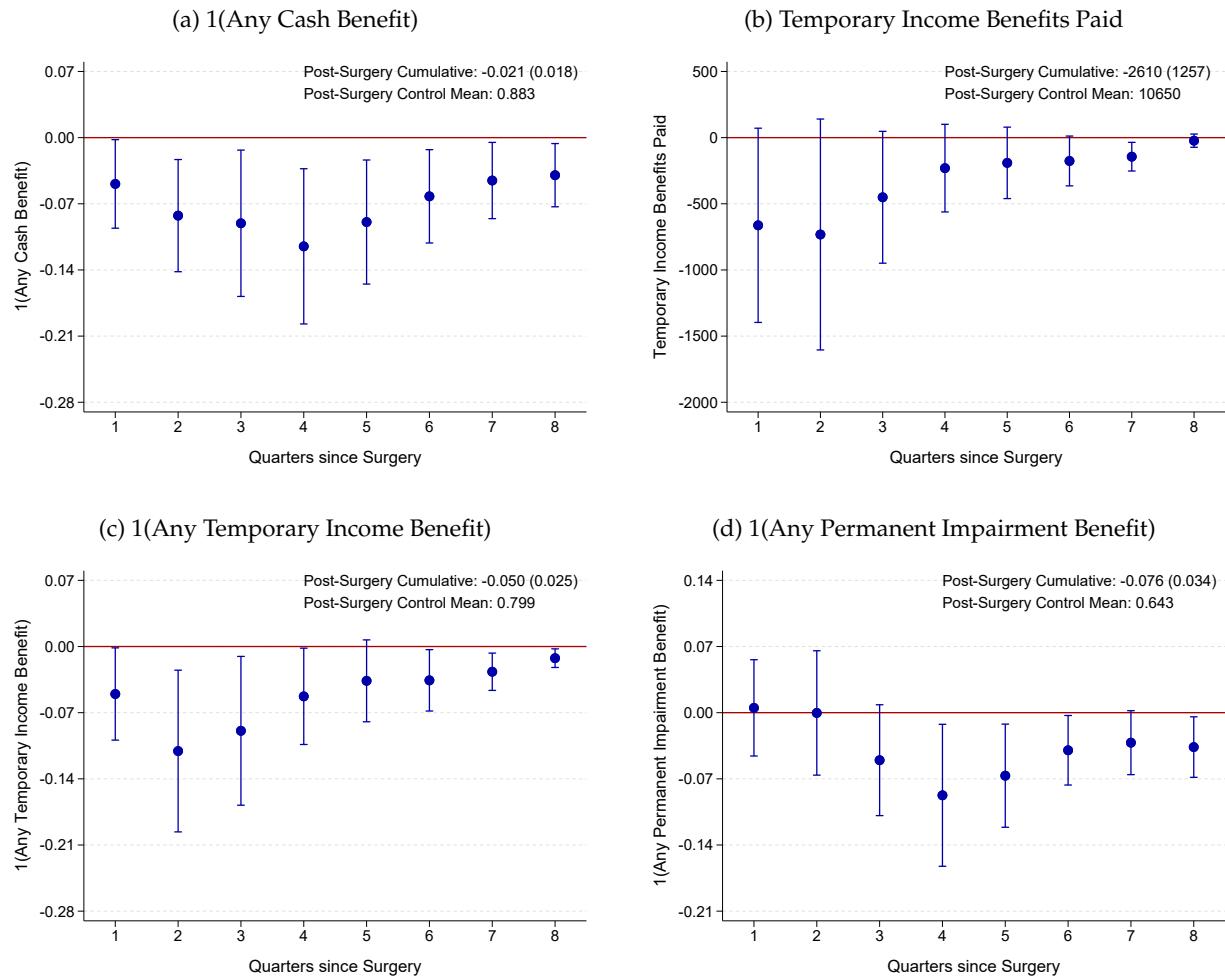

NOTES: This figure examines selection into receiving any target surgery by surgeons' minimally invasive intensity. Panel (a) compares the mean predicted probability of receiving a target surgery between out-of-sample and in-sample patients, obtained by estimating Equation (A1). Out-of-sample patients are those who consulted any surgeon in our analysis sample but did not receive a target surgery (and thus were not part of the analysis sample), whereas in-sample patients are those who were included in the analysis sample and received a target surgery within three months of their initial visit to the surgeon ($N_{\text{out-of-sample}} = 353,530$ and $N_{\text{in-sample}} = 70,090$). Panel (b) plots the predicted probability of surgery, residualized with respect to the baseline IV controls (i.e., age, sex, Hospital Referral Region, and surgery type by year), against 25 equal-sized bins of the surgeon intensity instrument among in-sample patients. The coefficient reported at the top of panel (b) is estimated from Equation (2) using the underlying patient-level data, whereas the line of best fit is obtained using the 25 plotted points. See Appendix Section C for further details on this analysis.

Figure A2: Dynamic Effects of Minimally Invasive Surgery on Health Care Services—Additional Outcomes

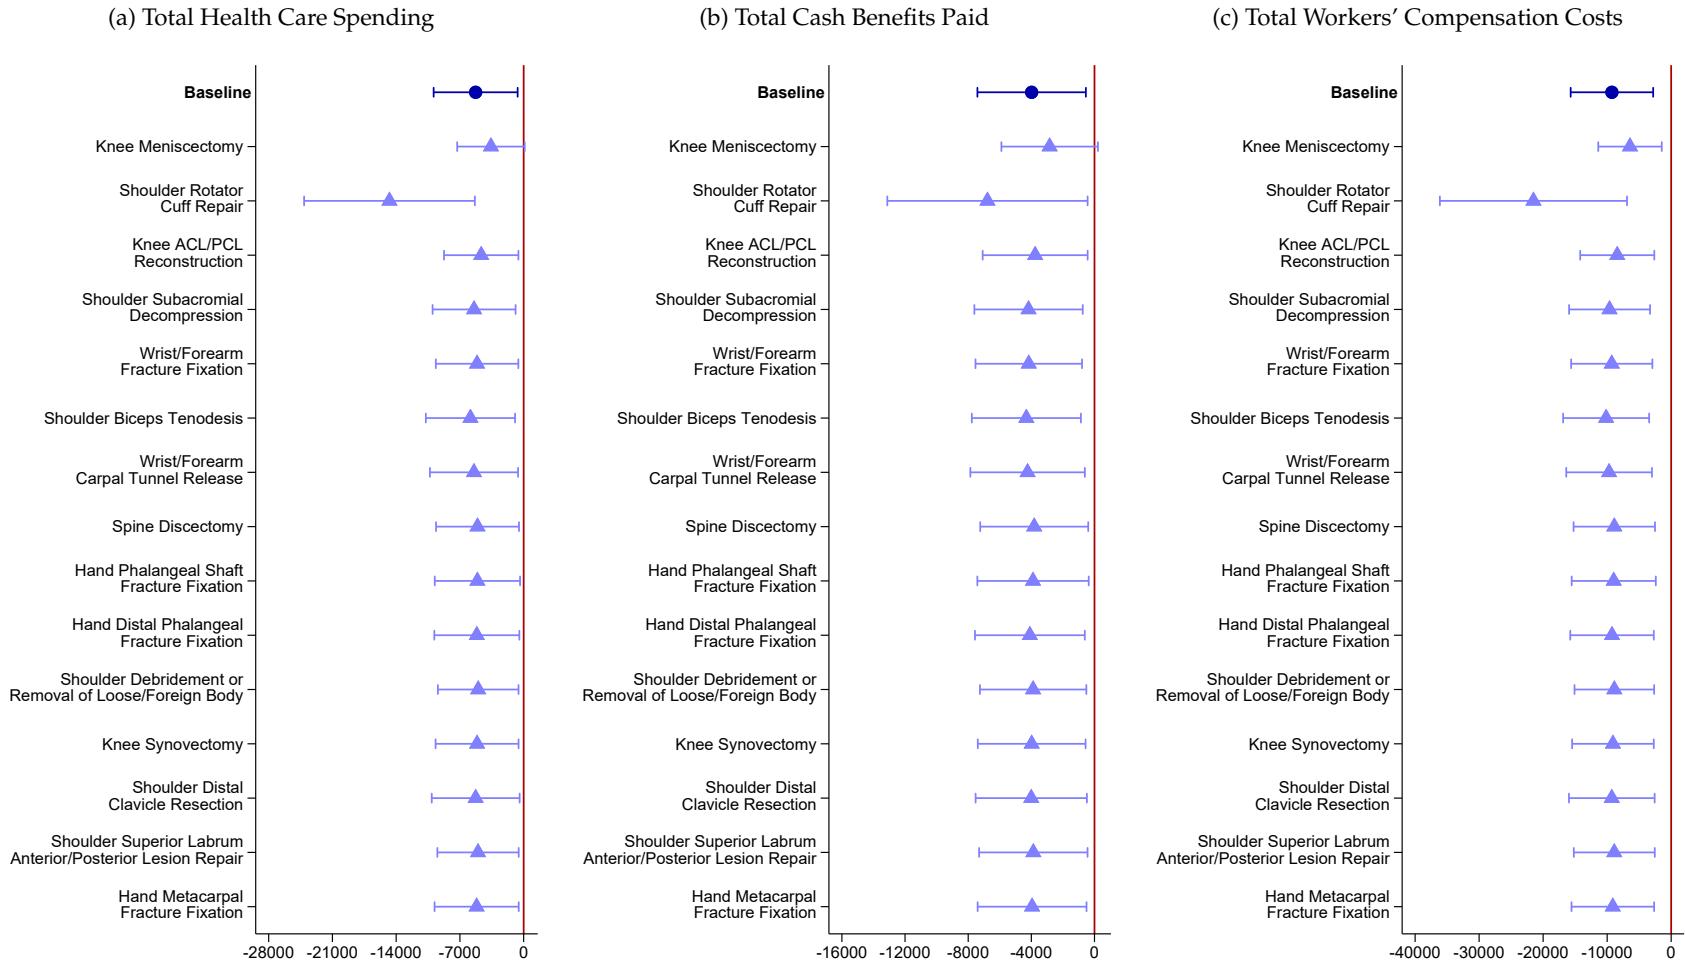

NOTES: This figure plots the estimated coefficients on the indicator for minimally invasive surgery from the IV specification outlined in Equations (1) and (2), along with 95% confidence intervals based on standard errors clustered at the surgeon level. Each quarter represents a separate regression, with the dependent variable measured over that quarter. The reported post-surgery cumulative effects are estimated using the dependent variables measured over all eight quarters. Post-surgery control means are calculated among patients who received open surgery.

Figure A3: Dynamic Effects of Minimally Invasive Surgery on Disability and Social Insurance Costs—Additional Outcomes

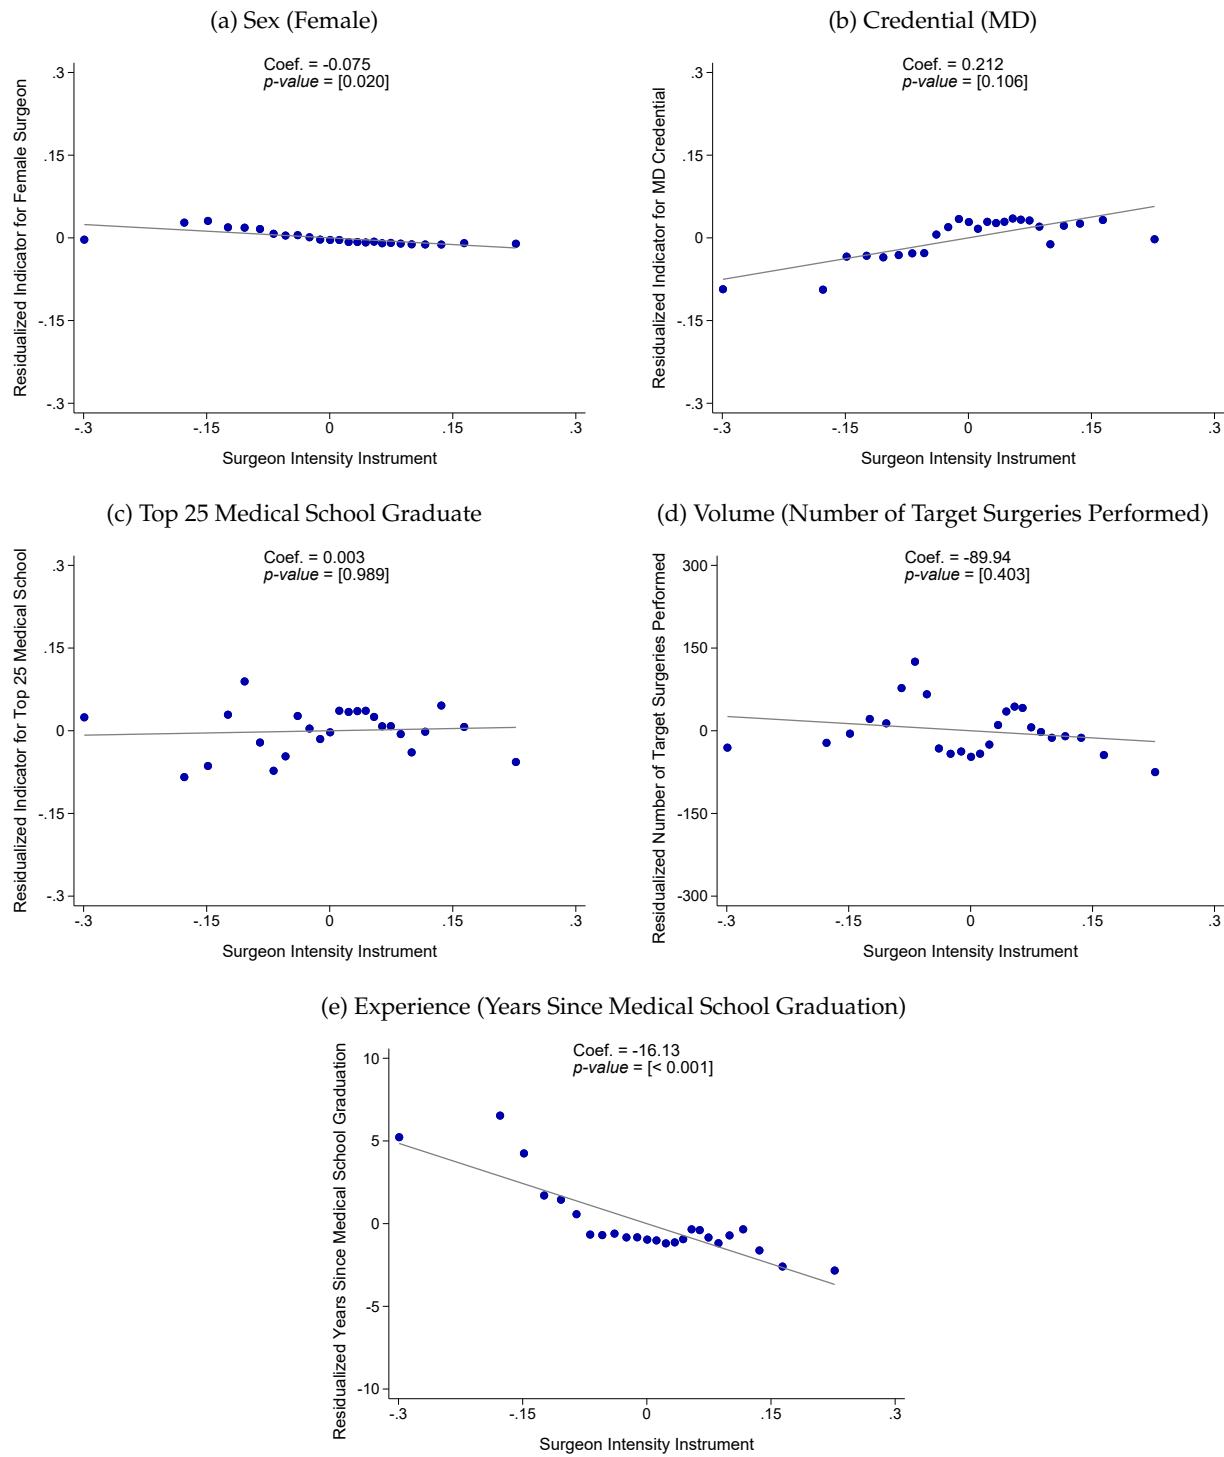

NOTES: This figure plots the estimated coefficients on the indicator for minimally invasive surgery from the IV specification outlined in Equations (1) and (2), along with 95% confidence intervals based on standard errors clustered at the surgeon level. Each quarter represents a separate regression, with the dependent variable measured over that quarter. The reported post-surgery cumulative effects are estimated using the dependent variables measured over all eight quarters. Post-surgery control means are calculated among patients who received open surgery.

Figure A4: Robustness—Excluding One of Top 15 Target Surgeries

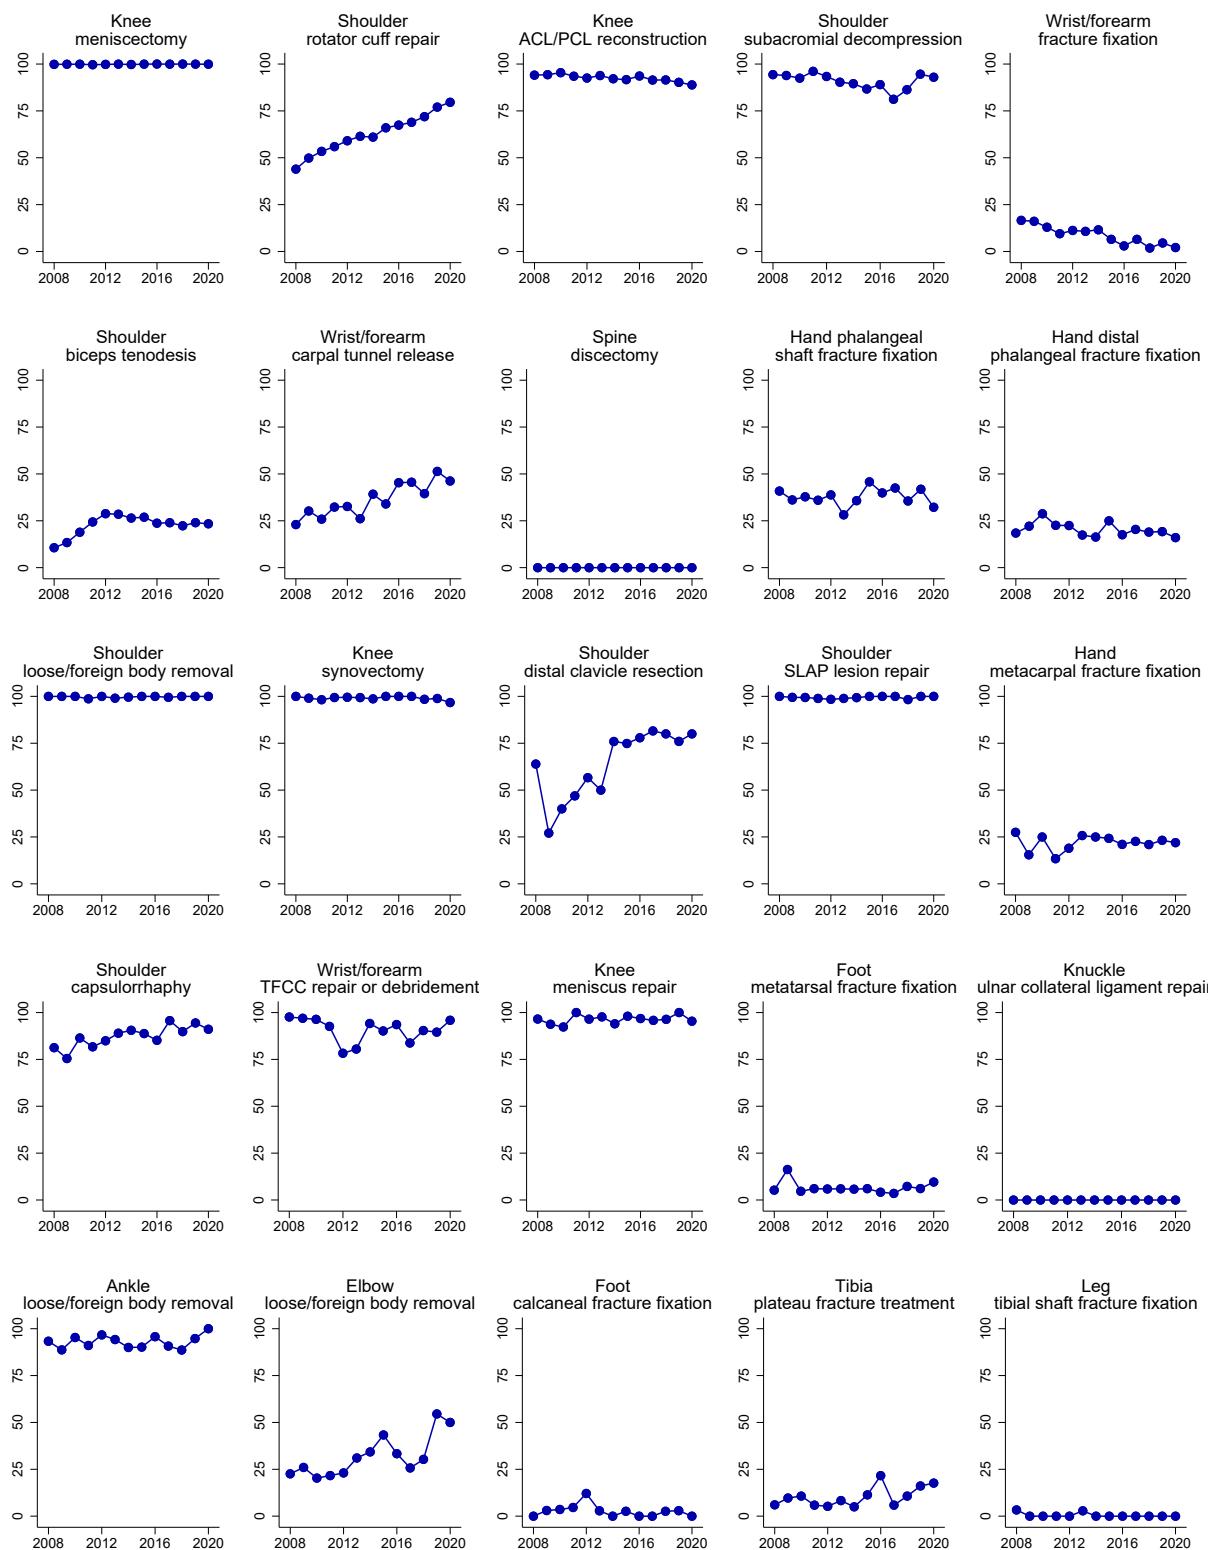

NOTES: This figure plots the estimated coefficients on the indicator for minimally invasive surgery from the IV specification outlined in Equations (1) and (2), along with 95% confidence intervals based on standard errors clustered at the surgeon level. The dependent variables are measured over the two years following surgery. For each panel, we first reproduce the baseline estimates (top row) and then re-estimate the IV specification excluding one of the 15 most common surgery types denoted on the vertical axis at a time.

Figure A5: Correlation Between Surgeon Characteristics and Intensity Instrument

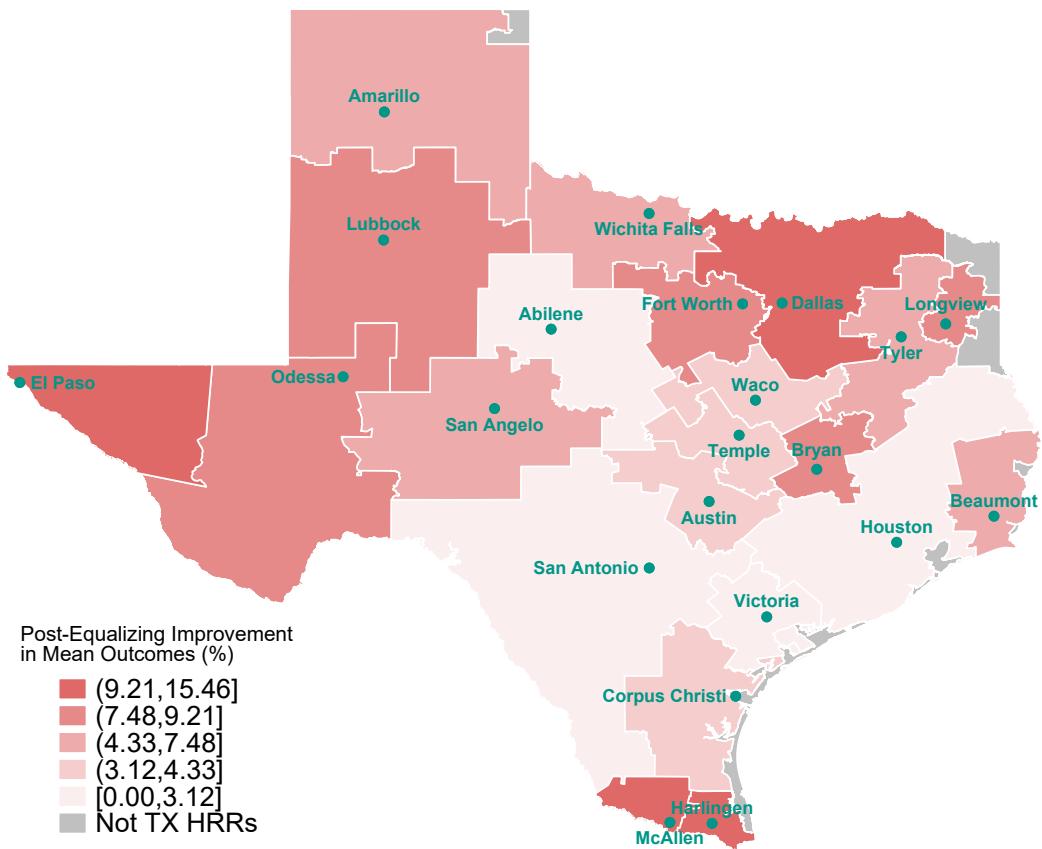

NOTES: This figure provides a graphical illustration of the correlation between surgeon characteristics and the surgeon intensity instrument. Each panel presents a binned scatter plot of the indicated surgeon characteristic, residualized with respect to the baseline IV controls (i.e., age, sex, Hospital Referral Region, and surgery type by year), against 25 equal-sized bins of the surgeon intensity instrument. The coefficients reported at the top of each panel are estimated from Equation (2) using the underlying patient-level data, whereas the lines of best fit are obtained using the 25 plotted points.

Figure A6: Trends in Share of Minimally Invasive Surgeries by Surgery Type

NOTES: This figure displays trends in the share of minimally invasive surgeries within our analysis sample, separately for each of the 25 most common surgery types. Panels are ordered by volume: the top row shows the five highest-volume surgeries (left to right), and each subsequent row shows the next five.

Figure A7: Potential Gains from Equalizing Share of Minimally Invasive Surgeries Across Hospital Referral Regions in Texas

NOTES: This figure displays the geographic distribution of the expected improvement in mean outcomes, grouped into quintiles, if the share of minimally invasive surgery is equalized across 22 Texas Hospital Referral Regions (HRRs) at the maximum observed level (76.3%).

F-Stat in Reverse Multivariate Regression	15.77			1.73		

NOTES: This table reports the estimated coefficients, standard errors, and p-values corresponding to Figure 3. Columns (1)–(3)—labeled OLS—report estimated coefficients from separate bivariate regressions of each characteristic on the indicator for minimally invasive surgery. Columns (4)–(6)—labeled IV—report estimated coefficients from separate regressions of each characteristic on the instrument, additionally controlling for the baseline IV controls (i.e., age, sex, Hospital Referral Region, and surgery type by year). The bottom row reports the F-statistic from an F-test of joint significance in reverse multivariate regressions of the minimally invasive indicator on all pre-surgery characteristics (OLS panel) and of the instrument on all pre-surgery characteristics and the baseline IV controls (IV panel). Standard errors are clustered at the surgeon level. See Appendix Section B.3 for more detail on the measures used for this analysis.

NOTES: This table reports the estimated coefficients from the first-stage specification outlined in Equation (2), estimated separately for each subgroup listed in the rows. Columns (1) and (2) report the estimated first-stage coefficients and standard errors. Columns (3) and (4) report the share of surgeries that are minimally invasive and the corresponding sample sizes.

Table A3: Heterogeneity by Pre-Surgery Patient Characteristics

	Baseline (1)	Sex	Age	1(First Treatment of Injury at ED)	1(Any Opioid Prescription)	First Day Health Care Spending

NOTES: This table reports the estimated coefficients on the indicator for minimally invasive surgery from the IV specification outlined in Equations (1) and (2), estimated separately for each subgroup denoted in the column headers. The dependent variables, measured over the two years following surgery, are indicated in each panel. Column (1) reports the baseline estimates for reference. Robust standard errors clustered at the surgeon level are reported in parentheses, p-values in brackets, and 95% confidence intervals in braces. Post-surgery control means are calculated among patients who received open surgery within each subgroup. These estimates are visually presented in Figure 7.

Table A4: Heterogeneity by Pre-Surgery Patient Characteristics—Supplemental Table

	Sex (1)	Age (2)	1(First Treatment of Injury at ED) (3)	1(Any Opioid Prescription) (4)	First Day Health Care Spending (5)
Panel A. Total Health Care Spending					
Difference	-2,641 (1,099) [0.016]	-5,333 (1,477) [< 0.001]	1,914 (1,129) [0.090]	-417.3 (1,053) [0.692]	1,863 (1,173) [0.112]
Panel B. Medical Spending					
Difference	-2,398 (989.3) [0.016]	-4,953 (1,334) [< 0.001]	1,429 (1,054) [0.175]	-604.1 (924.0) [0.513]	1,558 (1,045) [0.136]
Panel C. Prescription Drug Spending					
Difference	-242.3 (164.0) [0.140]	-379.9 (232.5) [0.103]	485.1 (169.9) [0.004]	186.7 (227.1) [0.411]	305.5 (186.6) [0.102]
Panel D. Total Cash Benefits Paid					
Difference	1,751 (1,127) [0.121]	-2,084 (1,387) [0.133]	-838.7 (1,233) [0.496]	95.11 (1,287) [0.941]	87.23 (1,120) [0.938]
Panel E. Days of Temporary Income Benefits					
Difference	-6.046 (9.627) [0.530]	-22.74 (12.26) [0.064]	5.194 (10.86) [0.633]	-0.277 (9.783) [0.977]	1.120 (9.884) [0.910]
Panel F. Permanent Impairment Benefits Paid					
Difference	795.6 (432.9) [0.066]	-765.1 (481.1) [0.112]	-133.3 (472.4) [0.778]	576.2 (501.0) [0.250]	232.8 (410.8) [0.571]
Panel G. Total Workers' Compensation Costs					
Difference	-889.8 (1,663) [0.593]	-7,417 (2,539) [0.004]	1,075 (2,030) [0.596]	-322.2 (1,841) [0.861]	1,950 (2,006) [0.331]

NOTES: This table supplements Appendix Table A3. Each column corresponds to one category and reports differences in the IV estimates between the two subgroups in that category, estimated as the former subgroup (e.g., female) minus the latter subgroup (e.g., male) in Appendix Table A3. Robust standard errors clustered at the surgeon level are reported in parentheses, and p-values are reported in brackets.

Table A5: Trends in Share of Minimally Invasive Surgeries by Surgery Type

	Number (1)	Share Minimally Invasive		Change in	
		2008–2009 (2)	2019–2020 (3)	Level (4)	Percent (5)
Knee meniscectomy	26,884	0.999	0.999	0.001	0.06%
Shoulder rotator cuff repair	17,646	0.469	0.783	0.314	67.04%
Knee ACL/PCL reconstruction	6,623	0.942	0.896	-0.047	-4.95%
Shoulder subacromial decompression	5,093	0.941	0.938	-0.003	-0.37%
Wrist/forearm fracture fixation	4,520	0.164	0.033	-0.130	-79.66%
Shoulder biceps tenodesis	3,658	0.120	0.237	0.117	97.30%
Wrist/forearm carpal tunnel release	2,774	0.266	0.488	0.222	83.38%
Spine discectomy	2,198	0.000	0.000	0.000	N/A
Hand phalangeal shaft fracture fixation	2,174	0.385	0.370	-0.015	-3.80%
Hand distal phalangeal fracture fixation	2,167	0.203	0.176	-0.027	-13.15%
Shoulder loose/foreign body removal	2,091	1.000	1.000	0.000	0.00%
Knee synovectomy	2,041	0.995	0.978	-0.017	-1.73%
Shoulder distal clavicle resection	1,910	0.455	0.780	0.325	71.44%
Shoulder SLAP lesion repair	1,901	0.997	1.000	0.003	0.27%
Hand metacarpal fracture fixation	1,440	0.215	0.226	0.011	5.22%
Shoulder capsulorrhaphy	1,434	0.784	0.928	0.144	18.36%
Wrist/forearm TFCC repair or debridement	1,219	0.973	0.927	-0.046	-4.69%
Knee meniscus repair	858	0.952	0.977	0.025	2.67%
Foot metatarsal fracture fixation	829	0.108	0.078	-0.029	-27.18%
Knuckle ulnar collateral ligament repair	683	0.000	0.000	0.000	N/A
Ankle loose/foreign body removal	677	0.910	0.974	0.063	6.97%
Elbow loose/foreign body removal	520	0.243	0.523	0.280	115.20%
Foot calcaneal fracture fixation	498	0.015	0.015	0.000	-2.94%
Tibia plateau fracture treatment	459	0.079	0.169	0.090	114.61%
Leg tibial shaft fracture fixation	457	0.017	0.000	-0.017	-100.00%

NOTES: This table reports changes in the share of surgeries that are minimally invasive between 2008 and 2020 for the 25 most common surgery types within our analysis sample. Column (1) reports the number of surgeries for each surgery type. Columns (2) and (3) report the mean shares that are minimally invasive in the first two years (2008–2009) and in the last two years (2019–2020) of the sample period, respectively. Columns (4) and (5) report the changes in these shares between the two periods, in absolute levels and percentage terms, respectively. These trends are visually presented in Appendix Figure A6.

Table A6: Impacts of Diffusion of Minimally Invasive Surgery on Outcomes

	Aggregated Impact of Diffusion on Outcomes (1)	Overall Change in Outcomes (3)	Share Explained by Diffusion (%) (4)	With 20% Faster Diffusion (5)
Panel A. Health Care Outcomes				
Total Spending				
Total Health Care Spending	-324.3	-1.87%	-2,161	15.01%
Medical Spending	-280.0	-1.69%	-1,664	16.82%
Prescription Drug Spending	-44.30	-6.16%	-497.0	8.91%
Other Outcomes

Permanent Impairment Benefits Paid	-84.32	-1.60%	-375.3	22.47%
1(Any Permanent Impairment Benefit)	-0.005	-0.73%	-0.063	7.49%
Permanent Impairment Severity Rating	-0.065	-1.87%	-0.520	12.53%
Total Workers' Compensation Costs	-569.2	-1.71%	-53.40	1065.79%

NOTES: This table summarizes the impact of the diffusion of minimally invasive techniques, drawing upon the baseline IV estimates and the observed change in the share of surgeries that are minimally invasive between 2008 and 2020. Column (1) reports the aggregated diffusion impacts, obtained by multiplying the baseline IV estimates by the overall growth rate in adoption (6.15 p.p.). Column (2) reports the estimated diffusion impacts in percentage terms relative to the control means reported in column (1) of Table 3. Column (3) reports mean changes in the indicated outcomes—net of surgery type fixed effects—between patients who had surgery in the first two years (2008–2009) and in the last two years (2019–2020) of the sample period. Column (4) reports the shares of these changes explained by diffusion (i.e., column (1) over column (3)). Column (5) reports the expected diffusion impacts if diffusion were counterfactually 20 % faster than observed.
